Metformin and Parameters of Physical Health

Mehmet Rami Helvaci¹, Hasan Kaya¹, Ali Borazan¹, Cahit Ozer¹, Mahmut Seyhanli² and Atilla Yalcin²

Abstract

Background  The prevalence of excess weight, including overweight and obesity, is increasing with a high cost on health in society.

Methods  Consecutive cases with excess weight, aged between 50 and 70 years and desiring weight loss, were divided into two subgroups according to wishes of patients about whether they prefer medication or just a diet. Metformin at a daily dose of 2,550 mg was given to the medication group.

Results  As for the very high prevalences, 84.8% (313/369) of cases at or above the age of 50 years were overweight or obese, 67.2% (248/369) of them had white coat hypertension (WCH) or hypertension (HT), 52.5% (194/369) of them had impaired glucose tolerance (IGT) or diabetes mellitus (DM), and 68.8% (254/369) of them had dyslipidemia. Initially 143 cases with excess weight preferred the diet and 162 of them preferred the metformin therapy. But 42 cases (25.9%) stopped the drug because of excessive anorexia. At the end of the six-month period, there were highly significant differences between the two groups according to prevalences of resolved WCH, hyperbetalipoproteinemia, hypertriglyceridemia, dyslipidemia, overweight, and obesity and a decreased fasting plasma glucose below 110 mg/dL (p<0.001 for all).

Conclusion  Due to the very high prevalences of excess weight and probably many associated disorders with the excess weight, including IGT or DM, WCH or HT, and dyslipidemia, above the age of 50 years, and the detected significant benefits of metformin on all of the above parameters, metformin treatment should be initiated in patients with excess weight in their fifties.

Key words: metformin, excess weight, fifty years of age

(Inter Med 47: 697-703, 2008)

Introduction

The prevalence of excess weight is increasing all over the world; it is a major health problem, as it is well recognized that excess weight causes a high cost on health even in early decades. Excess weight is a disorder characterized by increased mass of adipose tissue. The foremost physical consequences of excess weight are impaired glucose tolerance (IGT) or type 2 diabetes mellitus (DM), white coat hypertension (WCH) or hypertension (HT), dyslipidemia, and coronary heart disease (CHD) (1, 2). For example, atherogenic dyslipidemia is commonly seen in cases with excess weight, and it is characterized by an increased level of triglycerides or low density lipoprotein cholesterol (LDL-C), or a decreased level of high density lipoprotein cholesterol (HDL-C) in serum (1). Persons with excess weight have a higher prevalence of elevated blood pressure (BP) than lean persons, and some of the well-known complications of HT are left ventricular hypertrophy, CHD, heart failure, chronic renal failure, and stroke (3). On the other hand, excess weight is accompanied by several types of coagulation and fibrinolytic abnormalities, suggesting that it induces a prothrombotic and proinflammatory state terminating with atherosclerotic events all over the body (4). The chronic inflammation inducing endothelial dysfunction probably is the reason that excess weight causes increased atherogenicity (5, 6). As a supporting evidence of the role of inflammation in atherosclerosis, elevations of serum C-reactive protein (CRP) carry predictive power for the development of major cardiovascular events (7). In particular, excess weight is considered a strong factor in controlling the concentration of circu-
lating CRP concentrations because adipose tissue is involved in the regulation of cytokines (8), and individuals with excess weight have elevated levels of CRP suggesting that excess weight is a proinflammatory state (9). In addition to the above, excess weight is accompanied by some other medical complications including fatty liver, cholesterol gallstones, sleep apnea, osteoarthritis, and polycystic ovary disease, and the majority of people with excess weight have a clustering of these risk factors. Furthermore, excess weight is highly correlated with dietary intake of increased calories and fat, both of which have been linked to several types of cancer including breast, colon, and prostate (10). So excess weight, including overweight and obesity, is associated with an increased risk of death (11). On the other hand, metformin as an antihyperglycemic agent may be the first therapeutic option in treatment of type 2 DM with overweight or obesity, since it may prevent some vascular complications and mortality (12). It is effective enterally and not associated with hypoglycemia (13), thus it may be advantageous by diminishing risk of iatrogenic hypoglycemia. There are reports about some additional benefits of metformin on excess weight and many associated disorders in the literature (14, 15). Here we tried to elucidate whether or not metformin has some beneficial effects on excess weight and some associated disorders other than IGT or DM.

**Materials and Methods**

The study was performed in Internal Medicine Polyclinic of Dumlupinar University on routine check up patients between August 2005 and October 2006. Consecutive patients aged between 50 and 70 years were taken into the study to avoid debility-induced weight loss and metformin-induced lactic acidosis in elders. Their medical histories including HT, DM, dyslipidemia, and already used medications were recorded, and a routine check-up procedure including fasting plasma glucose (FPG), triglyceride, HDL-C, and LDL-C was performed. Patients with debilitating illnesses including type 1 DM, malignancies, acute or chronic renal failure, chronic liver diseases, hyper- or hypothyroidism, and heart failure were excluded to avoid their possible effects on weight. Body mass index (BMI) of each case was calculated by measurements of the same physician instead of verbal expressions. Weight in kilograms was divided by height in meters squared, and overweight was defined as a BMI of lower than 18.5, normal weight as 18.5-24.9, overweight as 25-29.9, and obesity as 30.0 kg/m² (2) or greater (1). Cases with an overnight FPG level of 126 mg/dL or higher on two occasions or already using antidiabetic medications were diagnosed when LDL-C was 160 mg/dL or higher and/or triglyceride was 200 mg/dL or higher and/or HDL-C was lower than 40 mg/dL. Office blood pressure (OBP) was checked after 5 minutes of rest in seated position with a mercury sphygmomanometer on three visits, and no smoking was permitted during the previous 2 hours. A 10-day twice daily measurement of blood pressure at home (HBP) was obtained in all cases, even in normotensives in the office due to the risk of masked HT after a 10-minute education about proper BP measurement techniques (16). The education included recommendation of upper arm while discouraging wrist and finger devices by using a standard adult cuff with bladder sizes of 12×26 cm for arm circumferences up to 33 cm in length and a large adult cuff with bladder sizes of 12×40 cm for arm circumferences up to 50 cm in length, and taking a rest at least for a period of 5-minute in the seated position before measurement. An additional 24-hour ambulatory blood pressure monitoring (ABP) was obtained just in cases with a higher OBP and/or HBP measurement. It was performed with oscillometric equipment (SpaceLabs 90207, Redmond, WA, USA) set to take a reading every 10-minute throughout the 24-hour. Normal daily activities were allowed, and subjects were told to keep the arm as relaxed during measurements. Eventually, HT was defined as a BP of 135/85 mmHg or greater on mean daytime (between 10 AM to 8 PM) ABP, WCH as an OBP of 140/90 mmHg or greater but mean daytime ABP of <135/85 mmHg, and masked HT as an OBP of <140/90 mmHg or HBP of <135/85 mmHg but mean daytime ABP of 135/85 mmHg or greater (16). Eventually, all cases with overweight or obesity at and above the age of 50 years and desiring weight loss were divided into two subgroups according to wishes of patients about whether they prefer medication or just with a low-calorie diet. The diet was planned as a 1,500 calorie containing diet which was poor in animal source foods but rich in vegetables and fruits divided in four to six small meals and snacks everyday. To simplify the diet, only one kind of animal source diet with a low amount was permitted daily and fruits were advised before meals to provide satiation with a freedom in amount. Additionally, foods that are high in sugars such as pastries, candy bars, pies, and candy were restricted. Metformin (850 mg tablet, Biokem, Turkey) at a dose of 2,550 mg/day in three divided dosages was given to the medication group orally, but the total dose was reached at the end of two weeks by increasing the dose 850 mg each week just to decrease some side effects of the drug. Patients were warned for the possible side effects of the drug including nausea, vomiting, anorexia, flatulence, sensation of a metallic taste in mouth, diarrhea, and abdominal discomfort. Patients were followed up for a period of six months with four-week intervals. At the end of this period, patients completing the follow-up were evaluated again, and prevalences of resolved WCH, hyperbeta lipoproteinemia, hypertriglyceridemia, dyslipidemia, overweight and obesity and prevalence of cases with a decreased
FPG below 110 mg/dL were detected in each group and compared in between. Student t-test and paired samples t-test were used as methods of statistical analysis.

### Results

The study included 369 cases between the ages of 50 and 70 years, but 56 of them were of normal weight and none of them was in the underweight range. Regarding the very high prevalences, 84.8% (313/369) of cases at and above the age of 50 years were overweight or obese, 67.2% (248/369) of them had WCH or HT, 52.5% (194/369) of them had IGT or DM, and 68.8% (254/369) of them had dyslipidemia (Table 1). Initially 143 cases with excess weight preferred the diet and 162 of them preferred the metformin therapy. But 42 cases (25.9%) stopped the drug therapy because of an excessive anorexia. No one left the study in the diet group. At the end of the six-month period, there were highly significant differences between the two groups according to the prevalences of resolved WCH, hyperbetalipoproteinemia, hypertriglyceridemia, dyslipidemia, overweight, and obesity and a decreased FPG below 110 mg/dL (p<0.001 for all) (Table 2). The mean weight loss was 10.3±5.3 kg (range 3 and 17) in the metformin group, whereas it was 3.2±4.7 kg (range 0 and 9) in the diet group. Although some cases progressed from obesity to overweight and from overweight to normal weight, there was no case going from obesity to normal weight in this period of time. The mean values of BMI, LDL-C, triglyceride, and HDL-C both in the metformin and diet groups before and after the therapies are shown in Tables 3, 4. On the other hand, nine cases (10.3%) of HT were masked HT, and the nine cases and 161 cases with WCH were diagnosed both via HBP and ABP, and no difference was observed between the two methods according to the total number of cases diagnosed. Mean systolic/diastolic OBP, HBP, ABP values and mean heart rates of the groups are summarized in Table 5. It was observed on ABP that the white coat effect was initiated by leaving home to come to the hospital.

### Discussion

Excess weight probably leads to structural and functional abnormalities of body systems. Recent studies have revealed that adipose tissue produces biologically active leptin, tumor necrosis factor-alpha, plasminogen activator inhibitor-1, and adiponectin, which are closely related to development of complications (17), so it is important in medical terms to specify the excess weight not only as one of the risk factors, but as ‘an obesity disease’. For example, cardiovascular field has recently shown great interest in role of inflammation in the development of atherosclerosis. Numerous recent epidemiological studies have indicated that inflammation plays an important role in pathogenesis of atherosclerosis and thrombosis (5, 6), and adipose tissue is involved in the regulation of cytokines (8). On the other hand, individuals with excess weight have an increased circulating blood volume as well as an increased cardiac output, thought to be a result of increased oxygen demand of the excess adipose tissue. The prolonged increase in circulating blood volume can lead to myocardial hypertrophy and decreased compliance in addition to the common comorbidity of HT. In addition to those, the prevalences of high FPG, high serum total cholesterol, and low HDL-C, and their clustering were all raised with increases in BMI (18). The combination of these cardiovascular risk factors eventually leads to an increase in left ventricular stroke work with a higher risk of arrhythmias, cardiac failure, and even a sudden cardiac death. Thus, the above prospective cohort study and some others showed that the BMI is one of the independent risk factors for stroke.

and CHD (18, 19). Eventually, risk of death from all causes, including cancers, increases throughout the range of moderate and severe excess weight both for men and women in all age groups (20).

In a previous study (21), we observed very high prevalences of WCH in society, 33.3% even in the second, 46.6% in the third, and 50.0% in the fourth decades of life, and prevalence of HT initially started to be higher than 40% in
the sixth and it reached up to 75% in the eighth decades of life. On the other hand, the prevalence of HT was detected only as 3% in the third, 8% in the fourth, and 21% in the fifth decades of life in the same study. The high prevalences of WCH in society have also been shown in some other studies (22, 23). So as a hypothesis, we came to propose that all HT cases, 75% in the eighth decade, may arise from the previously WCH cases, but this process takes a very long period of time reaching up to the normal life span of human being. So there would be some other significances of WCH for human health, thus in another study we evaluated the WCH not as a cause of HT or atherosclerosis alone but as a coexisting factor thus an alarming sign of something going bad for health (24). When we compared the sustained NT, WCH, and HT cases, prevalences of nearly all of the health problems including obesity, IGT, type 2 DM, hyperbetalipoproteinemia, hypertriglyceridemia, and dyslipidemia showed significant progressions from the sustained NT towards the WCH and HT groups, and the WCH group was found as a significant progression step in between (24). Additionally, plasma homocysteine levels were significantly higher (p<0.001) and left ventricle mass index was significantly greater in the WCH group compared to the NT cases (p<0.001), but both were significantly lower in the WCH group than the HT cases (p<0.001 and p=0.005, respectively) in another study (25). Similarly, the very high prevalences of dyslipidemia (68.8%), excess weight (84.8%), and WCH (43.6%) may indicate a very close relationship between them in the present study, since the dyslipidemia will probably come with excess weight, HT, type 2 DM, CHD,

* White coat hypertension † Office blood pressure ‡ Home blood pressure § 24-hour ambulatory blood pressure monitoring
and stroke-like health problems in the future. In other words, WCH may show an accelerating trend of gaining weight. By this way, the detected higher prevalences of WCH even in the second (33.3%) and in the third decades of life (46.6%) (21), although the lower prevalences of excess weight in these age groups may show the trend of getting weight, and the dyslipidemia may be another pioneer sign of excess weight in these cases. Similarly, we previously detected that WCH and HT have significantly lower prevalences in underweight than in normal weight and overweight cases, probably as another indicator of the effects of weight on BP (2). Thus, in the present study, probably due to the significantly reduced prevalences of overweight and obesity in the metformin against the diet groups, the resolved WCH cases were significantly higher in the metformin group (20.0% vs 65.1%, p<0.001). In other words, the ability of metformin to facilitate weight reduction or even stabilisation, at least according to our opinion, is probably its main action to prevent WCH. On the other hand, the relationship between excess weight and elevated BP is also described under the heading of metabolic syndrome, and clinical manifestations of the syndrome include abdominal obesity, dyslipidemia, HT, insulin resistance, and proinflammatory as well as prothrombotic states.

Biguanide was synthesized from two guanides which are the active components. Three widely used biguanides, metformin, buformin, and phenformin, were introduced in the late 1950s. Phenformin was withdrawn from clinical use in 1970s due to its close association with lactic acidosis (26). Metformin is currently being used in more than 90 countries worldwide. It is not metabolized in the body and 90% of the absorbed drug is eliminated as unchanged in urine. Plasma protein binding is negligible, so the drug is dialyzable. According to literature, antihyperglycemic effect of metformin is largely caused by inhibition of hepatic gluconeogenesis, increased insulin-mediated glucose disposal, and inhibition of fatty acid oxidation (27). Reduction of intestinal glucose absorption has been postulated as another possible mechanism of action, although data have been inconsistent (28). The precise mechanism of intracellular action of metformin remains uncertain. Interestingly, 25.9% (42 cases) of treated cases stopped the metformin therapy due to an excessive loss of appetite in the present study. Additionally, 14.1% (17 cases) of overweight or obese cases in the metformin group reached the normal weight or the overweight group, respectively, due to weight loss even in the absence of any given diet, whereas this ratio was only 3.4% (five cases) in the diet group. Thus, in our opinion, the major effect of metformin may be a powerful inhibition of appetite under the light of already known role of excess weight on HT, type 2 DM, dyslipidemia, and CHD-like disorders. Similar results indicating the beneficial effects of metformin on BMI, BP, and dyslipidemia have also been previously reported by other researchers (14, 15). Although thiazolidine derivatives may also exhibit an improvement in glucose and lipid metabolism, we think that the major component of metabolic syndrome is excess weight, and by breaking it we are also able to prevent most of its consequences on health. Thus, we preferred the presence of excess weight to initiate the metformin therapy in the present study. So prevention of excess weight with metformin will probably prevent not only IGT or DM but also most of the other consequences of excess weight on health.

Numerous side effects of metformin have been reported in the literature including nausea, vomiting, anorexia, diarrhea, sensation of a metallic taste in mouth, and lactic acidosis (29). Lactic acidosis is a very rare side effect with an estimated incidence of 0.03 per 1,000 patient-years, and it is typically observed in critically ill patients particularly those with sepsis or suicide attempt (29). Metformin causes lactic acidosis through two mechanisms, namely a shift in the intracellular redox potential away from an aerobic towards an anaerobic metabolism, and suppression of hepatic gluconeogenesis from lactate. Similarly, it was observed in another study that there is an increase in the plasma lactate concentration in absence of any substantial change in arterial pH in patients receiving metformin (30). The clinical significance of this accumulation of lactate without acidosis is unclear. It was previously shown in septic patients that the increased lactate concentrations resulted from an acceleration in glycolysis in excess of glucose oxidation (30). On the other hand, two reports by Lalau et al indicated that neither the degree of hyperlactatemia nor the accumulation of metformin is of prognostic significance for mortality, and the mortality appears to be linked to concurrent diseases rather than drug accumulation in the body (31, 32). Due to the very low risk of life threatening side effects of metformin, even we have never seen in our clinic before, it can be initiated for the majority of cases with excess weight, but clinicians must be careful with patients above the age of 70 years due to risk of comorbid disorders such as chronic renal failure and a tendency to develop sepsis.

In conclusion, due to the very high prevalence of excess weight and probably many associated disorders including IGT or DM, WCH or HT, and dyslipidemia above the age of 50 years, and the detected significant benefits of metformin on all of the above disorders, metformin should be initiated in individuals with excess weight in their fifties.
