A 15-year-old Indian girl presented to our centre with a history of two episodes of bilateral chorea, explained as Sydenham's Chorea, and an intense pain at the lower limbs. Magnetic resonance imaging (MRI) showed extensive bone lesions in the distal femur and proximal tibia at the right knee (Picture 1). Tibia bone biopsy was consistent with osteonecrosis. Laboratory tests revealed persistently high levels of antiphospholipid antibodies (aPL) with no other immunological findings of a connective tissue disease. We hypothesize that bone lesions due to osteonecrosis may be correlated with antiphospholipid antibodies as microvascular occlusions (1). Corticosteroid use and other conditions associated with osteonecrosis were excluded. Such bone lesions could develop in aPL patients, although they are uncommon (2). No other events (thrombosis or fetal losses) suggestive of antiphospholipid syndrome occurred. Therapy with low-dose aspirin was given and MRI 1 year later showed a definite reduction of bone lesions.
