Paradoxical Brain Embolism Induced by *Mycoplasma pneumoniae* Infection with Deep Venous Thrombus

Abstract

A 21-year-old man had sudden-onset right hemiplegia and aphasia with respiratory infection. A chest X-ray disclosed consolidation in both lungs and magnetic resonance imaging showed an embolism in the left middle cerebral artery. A pelvic computed tomography scan revealed deep venous thrombus in both femoral veins. Patent foramen ovale was detected by transesophageal echocardiogram. Antibodies to *M. pneumoniae* were highly elevated, and hypercoagulability was subsequently detected. This case suggests that the possible pathogenic mechanism for *M. pneumoniae* infection-related stroke might be paradoxical brain embolism with deep venous thrombus as a consequence of the hypercoagulability related to this infection.

Key words: paradoxical brain embolism, *Mycoplasma pneumoniae*, hypercoagulability, deep venous thrombus

Introduction

Although *Mycoplasma pneumoniae* infection is considered one of the potential risk factors of stroke (1), the underlying process leading to the stroke remains unclear. We present the first report of a case of paradoxical brain embolism with deep venous thrombus clearly determined to be caused by temporary hypercoagulability related to *M. pneumoniae* infection.

Case Report

An otherwise healthy 21-year-old male university student experienced sudden-onset, right side hemiparesis and aphasia during a bowel movement. He reported having an upper respiratory tract infection with high fever and dry-cough as well as bilateral leg swelling and pain for one week before this attack. He was referred to the emergency room three hours after onset.

On admission, he had fever (38.5°C), tachypnea (35 breaths/min), expiratory wheezes, and rhonchi and rales from both lungs. Expressive aphasia, lowered consciousness and severe hemiplegia on the right side were present. A chest X-ray revealed interstitial infiltration in both lungs. Four hours from onset, a diffusion-weighted magnetic resonance image showed large hyper-intense lesions in the left middle cerebral artery area (Fig. 1A). Magnetic resonance angiography disclosed complete occlusion of the left middle cerebral artery (Fig. 1B). A pelvic contrast-enhanced computed tomography scan revealed deep venous thrombus of both femoral veins (Fig. 1C). Transesophageal echocardiography examination using the contrast microbubble method (2) identified a patent foramen ovale as a right atrium to left atrium shunt only during the Valsalva maneuver (Fig. 1D). A Holter electrocardiogram and transthoracic echocardiography were negative, ruling out other potential causes of stroke, such as arrhythmia and valvular disease. The laboratory findings included elevated white blood cell count (9,900/μL) and elevated C-reactive protein (9.9 mg/dL). Platelet count was normal (24.4×10⁴/μL). Blood coagulation studies showed the following abnormal values: prolonged prothrombin time (17.4 sec, normal 9.5-13.5), prolonged partial thromboplastin time (61.4 sec, normal 25-40),
increased fibrin/fibrinogen degradation products (547 mg/dL, normal <100), increased thrombin-antithrombin III-complex (9.7 ng/mL, normal <3), increased D-dimer (30.6 μL, normal <1), increased antiphospholipid antibodies (16.5 U/mL, normal <10), increased IgM-anticardiolipin antibodies (220 MPL, normal <30), and slightly decreased protein C activity (66%, normal >70%). IgG-anticardiolipin, antiphospholipin, anticytoplasmic, antinuclear and anti-double/single stranded (ds/ss) DNA antibodies were not elevated. Cold agglutinins were positive (×1,024). The agglutination assay revealed strongly elevated M. pneumoniae antibodies (×2,560). Lumbar puncture showed a normal CSF leukocyte count (1×10^6 cells/L), total protein content (0.36 g/L), and glucose (0.51 g/L).

We diagnosed this case as paradoxical brain embolism with deep venous thrombus caused by hypercoagulability associated with M. pneumoniae infection. The patient was treated with minocycline and clarithromycin, and the anticoagulants heparin sodium and warfarin. The Mycoplasma pneumonia disappeared completely within a week. At three weeks, however, the thrombus in both femoral veins remained despite strong anticoagulant treatments; thus, a permanent filter was implanted in the inferior vena cava to prevent recurrent thromboembolism and he continued to take warfarin.

Six months after onset, the right hemiparesis and fluency had improved. The complete blood cell count and all biochemistry studies showed normal values including antiphospholipid antibodies and IgM-anti-cardiolipin antibodies. A follow-up magnetic resonance angiography showed that the occluded middle cerebral artery was not re-canalized. Two years following the attack the patient could walk and returned to the university.

Discussion

Stroke related to M. pneumoniae infection has been reported in several cases (3-9), mainly in children (3-5, 8). These reports proposed that the association is due to direct damage of the central nervous system (3, 6), or other mechanisms such as vasculitis resulting from post-infectious immunological disorders (4). These cases all reported normal coagulation values, although it is uncertain whether the timing of the coagulation tests was appropriate for detecting abnormal values. In adults, cervical artery vessel dissection and recent bacterial infections, including M. pneumoniae, were significantly correlated, but the definite cause was only speculative, and incomplete at that (7). To date, only two cases of ischemic stroke were reported with hypercoagulability after M. pneumoniae infection: a 13-year-old boy with a methylenetetrahydrofolate reductase gene mutant type had ischemic stroke with hypercoagulability after M. pneumoniae infection (8), and a 30-year-old man with left middle cerebral artery occlusion detected in cerebral angiography.
and associated with M. pneumoniae infection, showed hypercoagulability that suggested intravascular coagulation as a probable etiology (9). None of the above cases reported the presence of patent foramen ovale.

The present patient displayed severe hypercoagulability and increased IgM-anticardiolipin and antiphospholipid antibodies as well as femoral vein thrombosis on admission. Hypercoagulability associated with M. pneumoniae infection is not a rare phenomenon. It is suggested that the mechanism leading to hypercoagulability is related to the surface proteins, chemical mediators, and multiorgan proteins produced by M. pneumoniae, and that these molecules influence the role that hypercoagulability plays in molecular mimicry, postinfectious autoimmunity, and immune-mediated damage (10, 11). Similarly, the presence of transient antiphospholipid and anticardiolipin antibodies is well documented in the settings of many infections including M. pneumoniae (12-14). Recently, the coincidence of positive antiphospholipid and anticardiolipin antibodies, and hypercoagulability after M. pneumoniae infection was reported (14, 15). Antiphospholipid antibodies are a heterogeneous group of IgM and IgG antibodies directed against plasma proteins bound to phospholipid surfaces. The antiphospholipid antibody syndrome is used to describe patients who experience recurrent thrombosis in the setting of a persistent lupus anticoagulant or anticardiolipin antibodies. The precise mechanism by which these antibodies contribute to thrombosis is not fully understood (16, 17). In the present case, coagulation and increased antiphospholipid, IgM/IgG anticardiolipin antibodies returned to normal six months following the stroke attack; thus, we hypothesize that the antiphospholipid and IgM-anticardiolipin antibodies induced by the M. pneumoniae infection resulted in a temporary hypercoagulable state which contributed to the production of deep venous thrombus.

Furthermore, patent foramen ovale was detected by transesophageal echocardiogram (18) in our case. As the stroke attack occurred during a bowel movement, we suggest that the evacuation induced a situation similar to the Valsalva maneuver, which increases a right to left cardiac shunt (19). Taking these data together, we conclude that this stroke was induced by a paradoxical brain embolism via a patent foramen ovale from deep venous thrombus caused by M. pneumoniae infection. Development of thrombotic complications probably arose from antiphospholipid/anticardiolipin antibody formation associated with M. pneumoniae infection. The present case strongly suggests that other embolic stroke attacks seen particularly in young patients with M. pneumoniae infections may have similar mechanisms of paradoxical brain embolism and systemic hypercoagulability.
