**Abstract**

The DNA sequencing analyses of the 16S rRNA gene, *rpoB* and *hsp65* were conducted to characterize six strains that had been identified as *Mycobacterium xenopi* by DNA-DNA hybridization (DDH) for past ten years in our hospital. The results revealed *Mycobacterium heckeshornense* infection in one of the six cases. A 47-year-old man, who had been treated for pneumonia, had pulmonary nontuberculous mycobacterial disease. The sputa from the patient were culture positive for mycobacterium in three times. And it was diagnosed as *M. xenopi* by DDH method. Chest X-ray showed fibrocavitary lesion in right upper lobe was successfully treated with clarithromycin for four weeks.

**Key words:** *Mycobacterium heckeshornense*, *Mycobacterium xenopi*, DNA-DNA hybridization

**Introduction**

Since Roth et al reported the first case of *Mycobacterium heckeshornense* in 2000 (1), reports of its infection have been frequently published. There were three case reports of pulmonary disease and one case of tenosynovitis, lymphadenitis and lumbar spondylodiskitis (2-6). *M. heckeshornense* is a scotochromogenic and slowly growing organism, having similar properties to *Mycobacterium xenopi*. In recent years, of a new technique has been developed for bacterial analyses, such as DNA sequencing analyses of the genes in the 16S rRNA, *rpoB* and *hsp65*. Their analyses have led to the identification of numerous new bacterial strains. *M. heckeshornense* is one such example. It is important to clarify the clinical differences between the previously diagnosed strain and newly identified strain.

---

**Case Report**

A 47-year-old man was admitted to our hospital with pneumonia in December 2005. The patient had no past history of any significant illnesses, including chronic obstructive pulmonary disease. He had smoked about 30 cigarettes a day for 20 years. Serological tests for human immunodeficiency virus infection were negative. Chest X-ray (CXR) showed consolidation of the right upper lobe (RUL). The patient was treated with sulbactam sodium/ampicillin sodium (SBT/ABPC) for 5 days. Although a positive result of acid-fast bacteria was obtained two times in a row, no therapy was initiated, because the clinical presentation was consistent with community-acquired pneumonia and the PCR tests for both *Mycobacterium tuberculosis* (TB) and *Mycobacterium avium* complex were negative. After the patient was discharged from the hospital, the culture for mycobacterium was still positive. The DNA-DNA hybridization test (DDH mycobacteria, Kyokuto, Japan) identified that the mycobacterium was *M. xenopi*. Five months later, in May 2006, the patient was hospitalized with pneumonia again. Chest computed tomography (CT) revealed both the opacity in the right middle lobe and a fibrocavitary lesion in the RUL. Treatment with meropenem (MEPM) was started, and
4 days later it was changed to moxifloxacin. Smears test of sputum were negative for acid-fast bacteria. However, the mycobacterial culture test was positive and \textit{M. xenopi} was identified again. When two weeks passed after discharge from hospital, the CXR showed improvement of opacity in the right middle lobe, and the persistent fibrocavitary lesion. He complained of persistent cough, and he was treated with clarithromycin for 4 weeks. His symptoms were resolved, and the CXR showed improvement of the cavitary lesion. The mycobacterial culture test has been negative for 2 years since then.

**Discussion**

In the current cases of \textit{M. heckeshornense} disease, refractory pulmonary diseases have been reported. The percentage of the \textit{M. heckeshornense} patients with extrapulmonary lesions might be high in comparison with other nontuberculous mycobacterial (NTM) diseases. In the case of pulmonary disease, fibrocavitary formation was observed in three of four cases, including the present case that was similar to the disease pattern observed in \textit{M. xenopi} infection. According to the first report of \textit{M. heckeshornense}, it was resistant to isoniazid, and susceptible to rifampicin, amikacin, clarithromycin, ethambutol and ciprofloxacin (1). In the present case, the isolate was sensitive to isoniazid, rifampicin, ethionamide, cycloserine, levofloxacin and clarithromycin. The phenotype of drug susceptibility to isoniazid was different between the reference strain and the isolate. On the other hand, \textit{M. xenopi} usually shows susceptibility to aminoglycosides and ethionamide, but is not always susceptible to the first-line antituberculous drugs (7). British Thoracic Society (BTS) recommends using rifampicin and ethambutol for treatment of \textit{M. xenopi} as the first-line drugs. However, the treatment results of \textit{M. xenopi} infection have been disappointing.

Although only four cases of pulmonary disease caused by \textit{M. heckeshornense} have been reported until date, first-line antituberculous drugs were used in three cases because the phenotype of this organism was similar to \textit{M. xenopi}. \textit{M. heckeshornense} might be susceptible to other drugs including the new macrolides because clarithromycin was effective for treatment in our \textit{M. heckeshornense} case and the previous case, a 65-year-old woman, was susceptible to those drugs (4). Therefore, when bacilli are identified as \textit{M. heckeshornense}, we can have some choices of drugs in disease treatment. There have been two cases of pulmonary disease, so far as we know in Japan (8). One is a 51-year-old woman who showed progressive pulmonary disease and died after suffering from the disease for 14 years, and the other is a 72 year-old-man with pneumoniaosis. In this case, smear was positive in a total of 9 times and culture was positive in a total of 8 times within 2 months. However, the patient recovered and became smear- and culture-negative without any treatment. The highlights of this case are the fact that this organism does not always invade the lung tissues and might occur in the nature of a contaminant.

In Japan, NTM are identified by DDH method when TB is negative. The bacterial strain can be identified within several hours by measurement of the similarity between the specimen material DNA and 18 standard DNAs fixed to a 96-well plate. This method is based on the suggestion of modern taxonomic guidelines that homology among individual independent species should be less than 70% in optimal conditions, and has been available in Japan since 1980. Using sequence analyses of 16S rRNA gene, \textit{rpoB} and \textit{hsp65}, we attempted to characterize six strains that had been identified as \textit{M. xenopi} by DDH in the past ten years in our hospital. In one of six cases, the strain was found to be \textit{M. heckeshornense}. The differences of nucleotides between \textit{M. xenopi} (the standard strain from American Type Culture Collection) and \textit{M. heckeshornense} (our isolate) in genes of 16S rRNA, \textit{rpoB} and \textit{hsp65} were 24 bp in 448 bp, 1 bp in 306 bp and 8 bp in 419 bp, respectively (9-11). The DNA sequences in their genes between the standard strain of \textit{M. heckeshornense} and our isolate were identical. We found that sequence analyses are powerful tools for identification of mycobacterial strains in the clinical setting.

Although \textit{M. xenopi} disease is rare in Japan, it is suggested that patients infected with \textit{M. heckeshornense} may have been included at a constant rate in the cases that were diagnosed as \textit{M. xenopi} disease by DDH. Therefore, careful attention to this point is necessary in the future in Japan.

The authors state that they have no Conflict of Interest (COI).
