Physical Signs of Dehydration in the Elderly

Miyuki Shimizu¹, Kensuke Kinoshita², Kazuya Hattori², Yoshio Ota², Takao Kanai², Hiroyuki Kobayashi³ and Yasuharu Tokuda³

Abstract

Objective  Dehydration is a common condition and frequent cause of hospitalization in older people, despite the caregiver’s high attention in attempt to avoid its occurrence. In this study, various physical signs were examined as clinical signs of dehydration in elderly.

Methods  A prospective observational study was conducted in an acute care teaching hospital. Consecutive elderly patients who were admitted to the Department of Medicine were evaluated. Dehydration was defined as a calculated serum osmolality above 295 mOsm/L. The patients diagnosed as dehydrated or not dehydrated were observed for physical signs of dehydration. Data of blood and urine chemistry analysis were also compared between the two groups.

Results  A total of 27 elderly patients admitted with acute medical conditions were included in this study. For the physical signs, dry axilla had moderate sensitivity (44%) and excellent specificity (89%) to detect dehydration. Sunken eyes and delayed capillary refill time also showed relatively good specificity (83%). For laboratory data, the mean concentrations of serum sodium of the dehydrated group (146 mEq/L) was significantly higher (p<0.01) than those of the non-dehydrated group (134 mEq/L).

Conclusion  Physical signs of dehydration in elderly showed relatively good specificity but poor sensitivity. The evaluation of the axillary moisture could help assess dehydration as well as laboratory data analysis such as serum sodium concentration.

Key words: physical sign, dehydration, elderly, dry axilla

Introduction

Dehydration is a common condition in the elderly and exposes them to the risks of acute confusional states, delirium, renal failure, infection, falls, pressure ulcers and constipation (1, 2). The syndrome of dehydration is paid attention by their caregivers. Data from Medicare Provider Analysis and Review files compiled in 1991 by the Health Care Financing Administration (HCFA), identified dehydration as one of the 10 most common diagnoses reported for Medicare Hospitalization (3). Even in 2009, dehydration was listed as one of the 20 most common diagnoses reported by Agency for Healthcare Research and Quality (AHRQ).

The reason why the incidence of dehydration has not decreased in over a decade is that the means to recognize the symptoms of dehydration is not familiar to family members and care persons at home and there are also difficulties in determining dehydration even in nursing home residents. The common physical signs of dehydration are dry axilla (1), dry mouth, sunken eyes, decreased skin turgor, and delayed capillary refill time (4). These symptoms can be routinely identified by healthcare professionals, however they are not easily noticed by care persons at home and nursing homes.

In this study, we evaluated the relations between various physical signs and blood and urine test results, and revealed the most appropriate physical signs to determine dehydration in elders.

Materials and Methods

Subjects and setting

We studied patients aged 65 or older who presented to an acute care teaching hospital (Mito Kyodo General Hospital, Mito City, Ibaraki, Japan) and were consecutively admitted to the Department of Medicine with acute medical conditions. We conducted a prospective study over a seven-month span from December 2011. Patients excluded from the study were those with chronic kidney disease. Mito Kyodo General Hospital Ethics Committee approved the protocol. Research staff obtained written informed consent to participate in the current study from patients who were able to provide informed consent or from their designated representatives (if patients were unable to provide consent).

Methods

Subjects were classified as dehydrated or not dehydrated according to the criteria of calculated serum osmolality above 295 mOsm/L. The term of dehydration refers to losses of intracellular water that ultimately cause cellular desiccation and elevation of the serum osmolality (4). Thus, as a measure of dehydration, elevated serum osmolality was used in this study.

In the initial process of the evaluation, each patient was observed to have physical signs of dehydration as dry axilla, dry mouth, decreased skin turgor, sunken eyes, and delayed capillary refill time. These physical signs were taken by internal medicine residents. Consciousness level, dry mouth, decreased skin turgor, sunken eyes, and delayed capillary refill time were examined and recorded. Dry mouth was considered as present when both mucous membrane and tongue were dry by inspection. Dry axilla was examined by palpating bilateral axillary skin using the examiner’s second to fifth fingers. Sunken eyes were considered to be present when the bilateral eyeballs seemed abnormally sunken. Decreased skin turgor referred the slow return of skin to its normal position after being pinched between the examiner’s thumb and forefinger. Capillary refill time was determined by compressing the distal phalanx of the patient’s middle finger, positioned level with the heart, for 5 seconds and then timing the return of normal color to the finger. The upper limit of normal refill time was set at 2 seconds (4).

Next, the blood samples of the patient were obtained for blood tests as total protein concentration (TP), albumin concentration (ALB), blood urea nitrogen concentration (BUN), creatinine concentration (Cr), uric acid concentration (UA), sodium concentration (Na⁺), serum osmolality, and blood glucose concentration (BG). A BUN: Cr ratio (BUN/Cr) and osmolality were calculated. Osmolality was calculated with the following equation:

\[
\text{Calculated osmolality} = 2 \times \text{Na}^+ + \text{BG}/18 + \text{BUN}/2.8
\]

The urine sample of patient was then obtained for the urine tests as sodium concentration (Na⁺), creatinine concentration (Cr), and osmolality. The observation of physical signs, blood tests, urine tests were performed several times during hospitalization.

Statistical analysis

The statistical analysis was carried out with Student’s unpaired t test or an analysis of variance (ANOVA) using the SPSS version 18.0 for Windows (SAS Institute, Cary, NC, USA) when appropriate. A two-tailed P value of less than 0.05 was regarded as significant.

Results

Patients

Twenty-seven patients (16 men and 11 women) were recruited in the study sample. The patients diagnosed as dehydrated were 6 males aged 84.0±4.6 and 4 females aged 85.7±9.1. The patients diagnosed as non-dehydrated were 10 males aged 83.3±6.4 and 8 females aged 89.5±5.3 (Table 1). In the dehydrated group, the chief complaints were fever, dyspnea, diarrhea, anorexia, edema, abdominal pain, and dizziness. In the non-dehydrated group, the chief complaints were fever (10 patients), liver dysfunction (2 patients), and others (dyspnea, vomiting, disturbance of consciousness, cough, hemiplegia, and fatigue). During the hospitalization, 44% of patients in the dehydrated group died, while 17% in the non-dehydrated group died.

Physical signs

The prevalence of patients with positive physical signs of dehydration is shown in Table 2. The number of patients with decreased consciousness level was 1 for dehydrated, and 5 for non-dehydrated groups. Dry axilla was observed in 4 patients for the dehydrated group and 2 patients for the non-dehydrated group. Dry mouth was observed in about half of the patients in each group. Delayed capillary refill time and sunken eyes were observed in several patients of both groups. Decreased skin turgor was noted in 2 and 5 patients of the dehydrated and non-dehydrated groups, respectively.

Sensitivity was high in both dry axilla and dry mouth, while decreased consciousness level, sunken eyes, decreased skin turgor, and delayed capillary refill time were compara-
Cr ratio was 40 for dry axilla and 25 for wet axilla. The osmolality, and capillary refill time. This also affects the ability of urine in kidney (3). This results in the increase in plasma sodium concentration, serum osmolality, and capillary refill time. This also affects the ability of sweating (6) and saliva production. The degree of dehydration is correlated with changes in signs and symptoms of sweating (6) and saliva production. This suggests that dehydration may not be easily found out even if caretakers pay attention to dehydration. Dehydration is the result of a fluid imbalance due to a loss of too much fluid associated with the lack of thirst or due to a loss of too much fluid associated with the lack of condensation ability of urine in kidney (3). This results in the concentration of uric acid for the dehydrated group was 6.8 mg/dL higher than that of the non-dehydrated group was 5.3 mg/dL. Also and the concentration of serum sodium for the dehydrated group was 146.3 mEq/L as compared with the non-dehydrated group (134.7 mEq/L, p<0.01). Serum measured osmolality for the dehydrated group was significantly higher than that for the non-dehydrated group.

**Correlation between clinical examination and dry axilla**

The correlation between clinical examination and dry axilla is shown in Table 4. TP with dry axilla (7.0 mg/dL) was significantly higher than that with wet axilla (6.5 mg/dL), whereas ALB with dry axilla was significantly lower. BUN/Cr ratio was 40 for dry axilla and 25 for wet axilla. The osmolality for dry axilla (307.8 mmOsm) was significantly higher than that for wet axilla (289.5 mmOsm). However, there were no significant differences between two groups for urine tests.

**Discussion**

In the present study, we demonstrated that the physical signs could indicate the dehydration state. There were significant correlations between dry axilla and laboratory test results such as TP, ALB, BUN/Cr ratio and serum osmolality.

It has been reported that 10% of the geriatric patients admitted to long term care hospitals in Japan have low to moderate levels of dehydration in addition to other apparent disease conditions (5). This suggests that dehydration may not be easily found out even if caretakers pay attention to dehydration. Dehydration is the result of a fluid imbalance and inadequate circulating volume from either the consumption of too little fluid associated with the lack of thirst or due to a loss of too much fluid associated with the lack of condensation ability of urine in kidney (3). This results in the increase in plasma sodium concentration, serum osmolality, and capillary refill time. This also affects the ability of sweating (6) and saliva production. The degree of dehydration is correlated with changes in signs and symptoms classified as mild to severe dehydration.

In all patients, the most frequent main complaint was fever. One of the symptoms in moderate dehydration was fe-

**Clinical examination for the dehydrated and the non-dehydrated groups**

The results of clinical examination for both groups are shown in Table 3. For the blood tests, TP and ALB of the dehydrated group were slightly lower (6.8 mg/dL and 3.2 mg/dL, respectively) than those (7.0 mg/dL and 3.3 mg/dL, respectively) in the non-dehydrated group. The average BUN/Cr ratio was 28 for the dehydrated group and 24 for the non-dehydrated group. The concentration of uric acid for the dehydrated group was 6.8 mg/dL higher than that of the non-dehydrated group was 5.3 mg/dL. And also the concentration of serum sodium for the dehydrated group was 146.3 mEq/L as compared with the non-dehydrated group (134.7 mEq/L, p<0.01). Serum measured osmolality for the dehydrated group was significantly higher than that for the non-dehydrated group.

**Correlation between clinical examination and dry axilla**

The correlation between clinical examination and dry axilla is shown in Table 4. BUN/Cr ratio was 40 for dry axilla and 25 for wet axilla. The osmolality for dry axilla (307.8 mmOsm) was significantly higher than that for wet axilla (289.5 mmOsm). However, there were no significant differences between two groups for urine tests.

**Discussion**

In the present study, we demonstrated that the physical signs could indicate the dehydration state. There were significant correlations between dry axilla and laboratory test results such as TP, ALB, BUN/Cr ratio and serum osmolality.

It has been reported that 10% of the geriatric patients admitted to long term care hospitals in Japan have low to moderate levels of dehydration in addition to other apparent disease conditions (5). This suggests that dehydration may not be easily found out even if caretakers pay attention to dehydration. Dehydration is the result of a fluid imbalance and inadequate circulating volume from either the consumption of too little fluid associated with the lack of thirst or due to a loss of too much fluid associated with the lack of condensation ability of urine in kidney (3). This results in the increase in plasma sodium concentration, serum osmolality, and capillary refill time. This also affects the ability of sweating (6) and saliva production. The degree of dehydration is correlated with changes in signs and symptoms classified as mild to severe dehydration.

In all patients, the most frequent main complaint was fever. One of the symptoms in moderate dehydration was fe-
ver. However, 56% of patients in the non-dehydrated group complained of fever and thus the fever could not be regarded as the specific sign of dehydration. In the dehydrated group, 44% of the patients died during the hospitalization, whereas 17% of the patients died in the non-dehydrated group. This result is similar to the previous report in 1991 where 50% of elderly Medicare beneficiaries hospitalized with dehydration died within a year of admission (7).

In the physical signs, dry mouth was the most frequently observed sign in all patients, but its specificity was low. The decreased skin turgor was also observed in many patients with low sensitivity (Table 2). Geriatric patients are prone to a loss of total body water and therefore, many dehydrated patients showed the lack of saliva production and decreased skin turgor.

Only dry axilla indicated moderate sensitivity and excellent specificity (Table 2). This result is similar to the previous report that dry axilla has 50% sensitivity and 82% specificity, and both showed excellent specificity as a physical sign of dehydration. Dry axilla can be considered as a sign of dehydration. Decreased consciousness level and skin turgor showed a relatively low sensitivity with low odds ratios.

To determine the correlation between laboratory data and clinical diagnosis, we employed the common dehydration index such as TP, ALB, BUN/Cr, UA, Na⁺, and osmolality for blood tests, and Na⁺, Cr, and osmolality for urine tests. Na⁺, and osmolality of the blood tests showed significant differences between the dehydrated and the non-dehydrated groups. On the other hand, all indexes for urine tests did not show any significant differences.

Furthermore, we examined the correlation between dry axilla and the common dehydration index described above (Table 4). For TP, ALB, BUN/Cr, and osmolality, there were significant differences between those with dry axilla and without dry axilla. TP for dry axilla was higher than that of wet axilla, but ALB for dry axilla was significantly lower than that of wet axilla. The reason why TP increased along with the decrease of ALB was thought that ALB was strongly affected by nutrition state as well as dehydration. The patients with dry axilla were speculated to be malnourished.

## Conclusion

In conclusion, the present study demonstrated that the confirmation of the axillary moisture could indicate dehydration, as well as dehydration indexes such as serum sodium concentration, and osmolality. The dry axilla has the potentiality to be the simple method for detecting dehydration at home and in nursing homes.
