Abstract

Pneumothorax associated with chronic graft-versus-host disease (cGVHD) after stem cell transplantation is a rare complication. Autologous blood has been used successfully for pleurodesis, which was less toxic than chemical agents. However, when pneumothorax is resistant to pleurodesis, no other procedure is more effective and conservative. Here, we describe a case of myelodysplastic syndromes complicated with cGVHD-related pneumothorax. His pneumothorax has been resistant to pleurodesis using autologous blood and was treated successfully with fibrin glue sealant. In our limited experience, we believe the best success could be achieved when this method is used to treat persistent pneumothorax with cGVHD.

Key words: pneumothorax, chronic GVHD, pleurodesis, autologous blood patch, fibrin glue sealant

Introduction

Patients with air leak syndrome (ALS) associated with stem cell transplantation, including pneumothorax, mediastinal and subcutaneous emphysema, is one of the complications expected to increase in the future, and frequently have a fatal outcome (1, 2).

Persistent air leak is one of the intractable conditions of pneumothorax due to chronic graft-versus-host disease (cGVHD). It may lead to a longer in-hospital stay and impair the quality of life because of the uncomfortable chest drain tube. Toubai et al. reported that when the air leak cannot be treated appropriately, the patient has a very poor prognosis (2).

Pleurodesis might be preferable to surgery for the treatment of pneumothorax with cGVHD for patients with a poor condition. Autologous blood has been used successfully for pleurodesis (3), which was less toxic and harmful to lung tissue than conventional chemical agents. However, when pneumothorax is resistant to repeated pleurodesis, no other procedure is more effective and conservative.

Here, we present a case of pneumothorax with cGVHD after stem cell transplantation. His pneumothorax has been resistant to pleurodesis using autologous blood and was treated successfully with fibrin glue sealant, which recently has been applied by chest surgeons to stop air leakage from a resected lung surface during an operation. We believe the best success can be achieved when fibrin glue sealant methods are used to treat persistent pneumothorax with cGVHD after stem cell transplantation.

Case Report

A 21-year-old man, diagnosed with myelodysplastic syndrome (RAEB-2), initially treated with cytosine arabinoside...
A-C. Chest radiograph showing pneumothorax on both sides. D. Thoracography revealing the location of an air leak. E. Chest radiograph after treatment (day 514).

(100 mg/day for 14 days), underwent allogeneic bone marrow transplantation from his HLA-identical sibling donor after conditioning with 120 mg/kg of cyclophosphamide and total body irradiation (12 Gy fractionated in 6 doses). Post-transplant GVHD prophylaxis was with 3 mg/kg/day of cyclosporine (CSP) and short-term methotrexate (10 mg/m² intravenously on day 1 and 7 mg/m² intravenously on days 3, 6). Two months after transplantation he developed acute GVHD involving his skin (grade I), gastrointestinal tract (grade II) and liver (grade III), which was conclusive on biopsy, and then he was given 30 mg of prednisolone (PSL). He subsequently developed severe cGVHD affecting the lung. High resolution CT suggested interstitial lung disease with patchy areas of increased attenuation consistent with mosaic perfusion and bronchial dilatation. These are characteristic findings in bronchiolitis obliterans (BO). Lung function tests confirmed an obstructive and restrictive picture consistent with BO [FEV1.0 40.7%, %VC 93.0%, score 2 (NIH consensus)]. Bronchoalveolar lavage was negative for fungus, Pneumocystis Jirovecii and cytomegalovirus by culture and polymerase chain reaction analysis. He also developed oral cGVHD (xerostomia, score 1), and eyes cGVHD (dry eyes, score 1). Symptoms of cGVHD were controlled by increasing the dose of CSP up to 360 mg and 60 mg of PSL. However, 114 days after transplantation, he developed a productive cough, exertional dyspnea with right-sided chest pain. Chest radiographs demonstrated a large pneumothorax on the right side (Fig. 1A) and showed a newly-developed pneumothorax of the left side the next day (Fig. 1B). The insertion of a chest tube and drainage resulted in re-expansion of the right lung (Fig. 1B). Nevertheless, a persistent air leak continued on the left side (Fig. 1B). After 32 days of persistent air leak on the left side, a pleurodesis was attempted using 100 mL of autologous blood instilled via the chest drain. After a few days, we could remove the chest tube, however, symptoms such as cough, dyspnea and pain recurred two weeks later. Chest radiographs revealed a relapse of pneumothorax of the right side (Fig. 1C). After the insertion of a chest tube, autologous blood pleurodesis was repeated several times to the right side. Nevertheless, the persistent air leak remained refractory to the treatment. Then, a fibrin glue sealant approach was attempted. Briefly, 5 mL of 400 mg/mL fibrinogen, 375 U/mL factor XIII and 5 mL of 1,250 U/mL thrombin were drawn into separate syringes that were connected to the ports of the infusion catheter. Under X-ray fluoroscopy, the fibrin glue was placed at the site of the air leak (Fig. 1D). After a few days, the air leak resolved and the tube could be removed (Fig. 1E). The patient has now remained free of any air-leak problems for 10 months.

**Discussion**

Recently, Sakai et al. performed a multicenter retrospective study and identified ALS in 18 out of 1,515 recipients (1.2%) following SCT (1). They reported that cGVHD, second or subsequent SCT, male sex, age <38 years and FK-based GVHD prophylaxis were independent risk factors for ALS. Shin et al. reported that multiple factors, including TBI as a conditioning regimen and cGVHD after transplantation, especially from an unrelated donor, may be risk factors for the onset of pneumothorax combined with BO (4). Several reports have indicated that ALS following SCT is associated with severe cGVHD or noninfectious pulmonary complications (5-8), likely to be caused by BO as in the present case.

Whether an air leak is caused by spontaneous pneumothorax or GVHD-related BO, it can be managed conservatively with a chest drain left *in situ* and connected to a Heimlich valve (9), or by the injection of irritant agents into the pleu-
ral cavity, such as tetracycline, quinacrine, talc, or silver nitrate (10). Pleurodesis by the infusion of chemical agents via a chest tube is preferable to surgery for the treatment of pneumothorax when patients are in a poor condition. Also in the present case, since surgical options requiring general anesthesia were considered to be high risk due to the severity of the patient’s underlying lung condition, pleurodesis seemed preferable. However, chemical agents used for pleurodesis have serious documented risks such as tissue injury and irreversible damage. Thus, we decided to use autologous blood for pleurodesis.

Autologous blood has been used for pleurodesis for a number of years when spontaneous pneumothorax is recurrent and chronic (11-13). The pathophysiological mechanism mainly responsible for the sealing effect of blood is an inflammatory reaction in the pleural cavity that may contribute to the adhesion between the parietal and visceral pleurae like chemical agents. Further, it is likely that blood directly covers the lacerations in the visceral pleura and pulmonary parenchyma and seals the air leak (11). However the selection of first line therapy of pneumothorax should be judged according to the severity of disease, the previous report by Chadwick et al. that autologous blood patch has been successfully used for pneumothorax complicating cGVHD-related BO (14) encouraged us to select autologous blood.

In previous studies, different volumes of autologous blood were instilled via thoracostomy tubes, ranging from 50 to 250 mL, given on one to three occasions. It has been recommended that autologous blood should be given as few times as required to obtain the desired result (10). In the present case, a volume of 100 mL was used with no problems, and one procedure was already effective on the left-side pneumothorax. However, repetition treatment several times was not effective on the right-side pneumothorax. This was likely to have been due to low platelet counts and the low hematocrit of our patient. Furthermore, one of the reasons for the failure may have been because the lacerations in the visceral pleura and pulmonary parenchyma were so large that autologous blood could not cover and seal the air leak. It may have been better to use a fibrin glue method earlier because the therapeutic effect of autologous blood pleurodesis for our patient was not complete.

Recently chest surgeons have often applied fibrin glue to stop air leakage from a resected lung surface. Kinoshita et al. reported that when the fibrin glue is applied to a pneumothorax patient with an unexpanded lung, it is expected that the fibrin glue will first cover the air leak, subsequently produce lung expansion (15). Then, the fibrin glue sealant method was applied to the right side of the lung, which was resistant to repeated blood pleurodesis. The result has been fully satisfactory as described in “Case Report” section. Recently, Thistlethwaite et al. proposed this approach with fibrin glue for sealing the air leak of spontaneous pneumothorax (3). In their report, the air leak bubbling stopped or was greatly diminished in all patients. They used the fibrin sealant mixture containing 1,000 U/mL thrombin. Thus, here we used BOLHEAL (Teijin Pharma, Japan) 5 mL containing 1,250 U/mL thrombin. The advantage of this approach is direct visualization of the procedure under X-ray fluoroscopy and targeted sealing of the air leak without damaging healthy lung. However, the treatment failed because the fibrin often clotted inside the drain. To overcome these problems, Kinoshita et al. diluted the fibrin glue, allowing it to spread more easily from the drain tube into the pleural cavity, and also added contrast medium to facilitate checking by X-ray fluoroscopy (15).

Since the fibrin glue sealant method was dramatically effective in the present case, we strongly recommend this procedure for the treatment of intractable pneumothorax due to cGVHD-related BO. In addition, the fibrin sealant which we have used in this case was not autologous. We used a conventional fibrin sealant which includes human plasma and bovine-derived components. Thus, this fibrin sealant has the potential infective and antigenetic risk. In the future, it may be recommended to use a medical device for the preparation of an autologous fibrin sealant from the patient’s blood, such as the Vivostat system (Vivostat A/S, Alleroed, Denmark) (16).

Although this is the first report demonstrating the efficacy of the fibrin glue sealant method for pneumothorax due to cGVHD-related BO, we dare say that this method might be preferable to pleurodesis with autologous blood because pleurodesis is known to decrease respiratory function due to the adhesion of lung with the thoracic wall. In particular, it may become more severe and invasive for patients with lung cGVHD. On the one hand, the fibrin glue sealant method targets the visceral pleura and does not rely on the adhesion of lung to the thoracic wall to prevent recurrence (17). In addition, repeated autologous blood patches may increase the risk of bacterial contamination (18). In the future, it may become possible to avoid pleurodesis, considering the currently emerging interventional approaches, such as the fibrin glue sealant technique described here.

In conclusion, we believe that the best success could be achieved when the fibrin glue sealant method is used to treat persistent pneumothorax with cGVHD after stem cell transplantation.

The authors state that they have no Conflict of Interest (COI).
