Jejunal Lipoma Concealing Intestinal Adenocarcinoma: Don’t Always Regard CT Imaging Features Like Lipoma as Benign or Pseudomalignant Features

Zhang Shuo and LU Bin

Abstract

Lipomas are benign submucosal tumors composed of mature adipose tissue. Some authors have described patients with persistent abdominal pain who were misdiagnosed as intestinal adenocarcinoma and the diagnosis turned out to be a lipoma on histological examination. We discuss the case of a 57-year-old woman presenting with abdominal pain for 4 weeks. Intestinal adenocarcinoma was found by double-balloon enteroscopy (DBE), but at first only lipoma was found by CT scan. Therefore we want to emphasize that lipoma should not always be regarded as pseudomalignant features, sometimes lipoma conceals intestinal adenocarcinoma, and DBE may be a better way to discover malignancy.

Key words: lipoma, adenocarcinoma, submucosal tumors, intestinal obstruction, intussusception (Intern Med 51: 181-184, 2012) (DOI: 10.2169/internalmedicine.51.6497)

Introduction

Lipomas are benign submucosal tumors composed of mature adipose tissue. They occur anywhere in the gastrointestinal tract, but the incidence of lipomas occurring in both the small intestine and colon is rare (1-3). Although most intestinal lipomas are usually asymptomatic and detected incidentally, they are even a rarer source of severe symptoms such as obstruction, intussusception, and gastrointestinal bleeding. Those larger than 2 cm may occasionally cause abdominal pain, changes of bowel habits, rectal bleeding and bowel obstruction, intussusception or prolapse (4-6). Some reports have described patients with persistent abdominal pain who underwent laparoscopic right hemicolec- tomy for the presumptive endoscopic diagnosis of intestinal adenocarcinoma that turned out to be a lipoma on histological examination (7, 8). However, lipomas causing small intestinal intussusception could conceal intestinal adenocarcinoma. Misdiagnoses were inevitable in some cases by regarding the lipoma as benign or by pseudomalignant features.

We describe a patient with persistent abdominal pain who underwent partial enterectomy for the presumptive endoscopic diagnosis of multiple lipomas that turned out to be an adenocarcinoma on histological examination.

Case Report

A 57-year-old woman presented with abdominal pain and vomiting for a duration of 4 weeks. She denied melena, fever, or chills and her medical history did not include the consumption of alcohol or non-steroid anti-inflammatory drugs (NSAIDs). She had had symptoms intermittently for about 4 weeks. Then, the patient went to local hospital to test CT scan of abdomen. It showed the juncture of duodenum and jejunum with mural thickening and stratification, resulting in the target sign; furthermore, many round masses of fat density representing lipomas were found as the leading point of incomplete intestinal obstruction or intussusception in the jejunum and ileum. The doctor diagnosed the patient as having intestinal intussusception as a result of small intestinal lipomas and gave her traditional Chinese medicine (TCM) for treatment. There was no abdominal pain and vomiting after TCM treatment for a week. However, vomiting and abdominal pain appeared again 3 weeks previously.

Over the recent 2 weeks, the episodes of pain became more pronounced and the patient was not using any specific medication. So the patient came to our hospital.

After admission, physical examination revealed a temperature of 37°C, a pulse rate of 80 beats per minute (bpm), a blood pressure of 120/80 mmHg, and a respiration rate of 18 breaths per minute. The patient was pale-looking with abdominal tenderness in the right lower abdominal quadrant, without guarding or rebound and norm active bowel sounds were auscultated. Examination of the heart and lungs revealed no abnormal findings. Rectal examination revealed tarry fecal content. Turbid gastric content with chyme and bile were obtained on nasogastric aspiration. The initial laboratory workup was as follows: hemoglobin, 12.8 g/dL; white blood cells, 4,900/mm³ with a normal differential count; platelets, 200,000/mm³; blood glucose, 5.7 mmol/L; blood urea, 5.0 mmol/L; creatinine, 76 μmol/L; SGOT, 22 IU/L; SGPT, 28 IU/L; LDH, 135 IU/L; total bilirubin, 11.7 μmol/L; direct bilirubin, 2.7 μmol/L; and Na⁺, 136 mmol/L; K⁺, 3.9 mmol/L; CEa 3.2 ng/mL, CA199 65.5 U/mL, higher than normal. Fecal occult blood test was negative. A gastroscope was performed in order to explain the patient’s abdominal pain and vomiting. Without any complication. The patient was discharged without any complication.

Discussion

Lipoma of the gastrointestinal tract was first described by Bauer in 1757 (9). Lipomas are rare benign tumors of the small intestine with no malignant potential which are mostly encountered incidentally during investigation of the gastrointestinal tract for another reason, since they are usually asymptomatic (10). As small intestinal lipoma is relatively infrequent, it is even a rarer source of vomiting and gastrointestinal bleeding. Although the majority of these lesions are

**Figure 1.** The abdominal X-ray showed incomplete intestinal obstruction with pneumatosis and air-liquid in part of the small intestine. CT scan showed obstruction in the jejunum, resulting in the target sign; lipomas were found as the leading point of incomplete intestinal obstruction or intussusception within the lumen of the intussusceptum in the jejunum, ileum and ascending colon.
asymptomatic and detected incidentally during routine examinations or in a surgical specimen removed for various other reasons, on rare occasions they might present with symptoms depending on their size and location. The pathophysiology of the disease process leads to a complicated and confusing clinical picture of recurrent obstructive symptoms, chronic abdominal pain and lower gastrointestinal bleeding that may cause a delay in diagnosis and waste time. Lipomas of the small intestine are the second most common benign tumors next to leiomyomas (11). Their location and the peak age vary, however approximately 50% are found in the ileum, and the sixth to seventh decades of life are considered to be the most risky period (10, 11). In general, lipomas are defined to originate in the submucosal layer and are usually solitary, with variable sizes ranging from 1 cm to 30 cm (12). They usually appear as a sessile protrusion into the lumen of the intestine. Multiple lipomas are rare and noted only in 10-20% of cases. They can cause symptoms when the size exceeds 2 cm including bleeding with anemia, constipation, change in bowel habits, abdominal pain, intestinal obstruction and rarely intussusception. Lipomas of the large bowel are uncommon fatty neoplasms with a reported incidence ranging between 0.2% and 4.4% (13).

Adenocarcinoma of the small intestine is a relatively rare malignancy as compared to the other malignancies of the gastrointestinal tract, but it represents 50% of small intestinal malignant tumors. The clinical signs and symptoms may vary with the tumor site, size, and existence of ulceration. The common presenting signs and symptoms in the present patient were nausea, vomiting, abdominal pain, melena, weight loss, anemia, and a palpable mass, none of which was pathognomonic for small bowel tumors. Nonspecific presentation and infrequent occurrence often lead to a delay in diagnosis and consequent poor prognosis. In recent years, the diagnosis for small intestinal malignancy has been improved as a result of advances in endoscopic technologies such as DBE (14). DBE is a new technique that enables deep intubation of the endoscope into the small intestine; it is a safe procedure and has a high diagnostic and therapeutic yield to make a preoperative histological diagnosis of intestinal malignancy. Confirming malignancy using DBE in equivocal cases may greatly increase both the compliance of patients for an operation and confidence of the physician planning a surgical resection.

Some authors have described patients with persistent abdominal pain who underwent laparoscopic right hemicolectomy for the presumptive endoscopic diagnosis of intestinal adenocarcinoma that turned out to be a lipoma upon histological examination (7, 8). But, in the present case, the doctor of the local hospital thought the obstructive periods and abdominal pain of the patient might be attributed to luminal obstruction which might be induced by lipomatous develop-
The authors state that they have no Conflict of Interest (COI).
