CASE REPORT

A Case of Painless Thyroiditis in a Very Early Stage of Pregnancy

Abstract

We report a case of painless thyroiditis detected during the first trimester of pregnancy. A 29-year-old Japanese woman was hospitalized because of thyrotoxicosis and she was confirmed to be pregnant. The gestational age was 4 weeks. Blood examinations revealed negative TSH receptor antibodies, however, we started potassium iodide because we were unable to rule out Graves’ disease. Thyroid hormone levels were normalized in 3 weeks and remained low even after discontinuation of medication. She received replacement therapy with levothyroxine sodium hydrate till 3 months after delivery. Painless thyroiditis can be one of the differential diagnoses of thyrotoxicosis in a very early stage of pregnancy.

Key words: thyrotoxicosis, pregnancy, painless thyroiditis

Introduction

Thyrotoxicosis during pregnancy can adversely influence not only the mother but also the fetus. To avoid these influences, it is essential to identify the underlying disease responsible for thyrotoxicosis during pregnancy.

Thyrotoxicosis during the first trimester of pregnancy is mostly attributable to Graves’ disease or gestational transient hyperthyroidism [GTH, also called gestational transient thyrotoxicosis (GTT)]. GTH is seen more frequently in Asians than in other races. According to a report from Belgium, the prevalence of Graves’ disease is about 0.2% while that of GTH is 2% to 4% (1). Yeo et al reported that Graves’s disease was seen in 1.2% and GTH in 11% of Singaporean women in the first trimester of pregnancy (2). Graves’ disease requires immediate treatment, while GTH can be viewed as a physiological phenomenon that subsides spontaneously without treatment in most of the cases.

Painless thyroiditis is a disease causing thyrotoxicosis during the postpartum period or in other conditions. However, according to our literature search, no cases of painless thyroiditis developing during pregnancy have been reported, and this disease is not generally considered in the differential diagnosis of thyrotoxicosis during pregnancy. Because painless thyroiditis also subsides spontaneously, it is important that this disease is distinguished from Graves’ disease. We present herein a case of thyrotoxicosis detected during the first trimester of pregnancy and diagnosed with painless thyroiditis.

Case Report

The patient was a 29-year-old Japanese woman. In February 2007, she underwent hysterosalpingography for detailed examination of infertility. She became pregnant 4 months later, but her pregnancy ended with a miscarriage at the gestational age of 5 full weeks. Nine months after the miscarriage, she became aware of palpitation, excessive sweating, and hyperphagia, followed by finger tremor and nausea. Two weeks after the appearance of these symptoms, she consulted the Showa University Fujigaoka Hospital. During the first examination, she showed slight swelling of the thyroid but she had no thyroid tenderness or vascular murmur. Exophthalmos was absent. There were no signs of heart failure. She had no family history of thyroid disease. Laboratory tests revealed thyrotoxicosis: FT3 28.55 pg/mL (2.0-4.5 pg/mL), FT4 8.49 ng/dL (0.7-1.8 ng/dL), and thyroid stimu-
Painless thyroiditis is a destructive thyroid disease with transient thyrotoxicosis usually followed by transient hypo-
thyroidism. Postpartum painless thyroiditis is a typical form of this condition, and its onset is triggered by delivery. The onset of this disease is considered to be attributable to an immunological rebound phenomenon, i.e., sudden loss of immunological tolerance (seen during pregnancy) after delivery and the resultant activation of immune function above the normal level (4). It usually develops at 1-6 months after delivery. Cases of painless thyroiditis developing after pregnancy loss have also been reported (5).

Factors possibly triggering the onset of painless thyroiditis include a sharp reduction in high blood steroid levels [following withdrawal of steroid therapy (6), surgery for Cushing syndrome (7)] and interferon therapy (8). Changes in immune processes appear to be involved in this disease trigger, but the exact mechanism remains to be clarified.

In the present case, thyrotoxicosis was detected at a very early stage of pregnancy. Palpation and ultrasonography ruled out subacute thyroiditis or an autonomously functioning thyroid nodule. GTH was also ruled out on the basis of gestational age and the blood HCG level. As thyroid scintigraphy was not applicable in the pregnant case, we judged Graves’ disease to be highly probable, because no cases of painless thyroiditis during pregnancy had been previously reported. For this reason and in view of the severe thyrotoxicosis, we began administration of PTU before the TRAb data became available. Methods for distinguishing Graves’ disease from painless thyroiditis include ultrasonographic evaluation of blood flow in addition to TRAb measurement and scintigraphy. Patients with Graves’ disease reportedly show increased blood flow, while those with destructive thyroiditis, such as painless thyroiditis and subacute thyroiditis, present with reduced blood flow (9, 10).

In the present study, TRAb was negative, and Doppler study revealed no increase in blood flow. There were few findings supporting the diagnosis of Graves’ disease, and the patient showed a continuance of hypothyroidism despite medication having been discontinued after about 3 weeks of treatment for thyrotoxicosis. The patient was diagnosed as having painless thyroiditis.

Factors reportedly causing thyrotoxicosis during pregnancy include not only GTH and Graves’ disease but also subacute thyroiditis and autonomously functioning thyroid nodules (11, 12). To date, however, no cases of painless thyroiditis during pregnancy have been reported. This may reflect the influence of immunological tolerance during pregnancy, but it is also possible that even in pregnant women with this disease, it cannot be definitively diagnosed because of inability to perform thyroid scintigraphy during pregnancy, which could account for the absence of reports on such cases.

In the present case, thyrotoxicosis was detected during pregnancy. Detection of the disease in a very early stage of pregnancy indicated, however, that the mechanism underlying the development of painless thyroiditis had occurred before pregnancy and that the pregnancy had been established during the course of painless thyroiditis, rather than the disease developing during pregnancy. One possible trigger for the onset of painless thyroiditis was the spontaneous abortion 9 months earlier. Marqusee et al reported cases of painless thyroiditis diagnosed from 3 to 11 months after pregnancy loss (5).

In cases with TRAb negative thyrotoxicosis during the first trimester of pregnancy, it is advisable to consider the possibility that the pregnancy was established in the presence of painless thyroiditis and to conduct detailed examinations, using Doppler ultrasonography. After these steps, it would be necessary to follow the courses of thyroid hormones closely, bearing in mind the possibility of the subsequent onset of hypothyroidism.

The authors state that they have no Conflict of Interest (COI).
