Low Cardiac Output in a Case of Constrictive Pericarditis with Protein-losing Enteropathy

Shohei Kikuchi, Nobuyuki Ohte, Kazuaki Wakami, Toshihiko Goto and Genjiro Kimura

Abstract

A man in his late seventies was suffering from right-sided pleural effusion and worsening leg edema. He was diagnosed with a rare case of secondary protein-losing enteropathy caused by constrictive pericarditis (CP) using technetium 99m-labeled human serum albumin abdominal scintigraphy and comprehensive Doppler echocardiography. We herein report the importance of evaluating a low cardiac output in addition to established Doppler echocardiographic findings for making a diagnosis of CP coexistent with protein-losing enteropathy.

Key words: constrictive pericarditis, protein-losing enteropathy, low cardiac output, Doppler echocardiography

Introduction

Constrictive pericarditis (CP) is caused by scarring and the consequent loss of normal elasticity of the pericardium, thus resulting in enhanced interdependence of both ventricles and impaired diastolic filling. Although patients with this disease typically present with signs and symptoms of right-sided heart failure and/or low cardiac output, the symptoms are often nonspecific and develop slowly, so that making an accurate and prompt diagnosis of CP is sometimes difficult. Doppler echocardiography is the initial imaging modality used to make an anatomical and hemodynamic diagnosis of CP. We herein report a rare case of CP coexistent with protein-losing enteropathy. In this case, Doppler echocardiography was used to make the diagnosis of CP along with the findings of low cardiac output and restrictive ventricular filling.

Case Report

A man in his late seventies was admitted to our hospital due to abnormal liver function tests and accumulation of a right-sided pleural effusion. He had been treated with an oral diuretic before admission. On admission, his heart rate was 80 beats/min and his blood pressure was 110/60 mm Hg. A physical examination revealed regular heart sounds without any murmurs. The patient’s external jugular veins were distended. A positive hepatojugular reflux was observed, and the liver was descended 3-4 cm below the right costal margin. Electrocardiogram showed a normal sinus rhythm with low voltage in the limb leads. Chest radiograph revealed a right-sided pleural effusion without pulmonary congestion. The laboratory findings are shown in Table. The patient’s serum albumin level was found to have decreased, the serum creatinine level was in the normal range and no urinary protein was detected. Abdominal computed tomography did not show any findings of liver cirrhosis. After admission, the patient received the intravenous injection of furosemide to treat the pleural effusion and leg edema, and his blood pressure remarkably decreased to 60 mmHg in systole; however, after discontinuation of furosemide, the patient’s blood pressure recovered to the original level. Fluid obtained with thoracentesis exhibited a transudate nature. A low serum albumin concentration with an absence of nephrotic syndrome, liver cirrhosis or malnutrition suggested a diagnosis of protein-losing enteropathy. Technetium 99m-labeled human serum albumin-diethyleneetriaminepenta-acetic acid (99mTc-HSAD) scintigraphy revealed an accumulation of radionuclide in the intestines in

the right side of the abdomen (Fig. 1A). Therefore, the hypoalbuminemia was ultimately diagnosed to be the result of protein-losing enteropathy. With regard to the differential diagnosis of protein-losing enteropathy, gastrointestinal amyloidosis and malignant lymphoma of the intestines were both proven to be negative on endoscopic and histological examinations.

Contrast-enhanced cardiac computed tomography disclosed a thickened pericardium (Fig. 1B). Two-dimensional echocardiography also showed thickened pericardium around the heart (Fig. 1C), a normal left ventricular (LV) cavity size (end-diastolic dimension: 36 mm and end-systolic dimension: 25 mm) and a normal wall thickness as well as a preserved LV ejection fraction (61%). Both the right atrium (RA) and the left atrium (LA) were mildly distended (Fig. 1D). The maximum diameter of the LA at end-systole in the apical four-chamber view was 43 mm. The calculated LA volume and the LA volume indexed to the patient’s body surface area at end-systole were 60.5 mL and 39 mL/m$^2$, respectively. The peak early to peak late velocity ratio (E/A) in transmural flow was >1.0, and the early diastolic mitral annular velocity at the septal corner was exaggerated (12.6 cm/s) (Fig. 2A, 2B). Significant decreases in early diastolic transmural flow velocity and significant increases in the early diastolic transthoracic flow velocity during inspiratory were observed (Fig. 2C). The alteration of the early diastolic transmural flow velocity during respiration was 29% and that of early diastolic transthoracic flow velocity was 30%. The inferior vena cava was found to be distended (19 mm) with a poor respiratory change. The velocity-time integral at the LV outflow tract increased to 16.0 cm, and the cardiac output and cardiac index increased to 4.43 L/min and 2.86 L/min/m$^2$, respectively.

Discussion

Protein-losing enteropathies are characterized by an excessive loss of serum proteins into the gastrointestinal tract, resulting in hypoalbuminemia, edema, ascites and pleural effusion. Dilated intestinal lymphatic ducts are observed not only in patients with primary lymphangiectasia, but also in those with secondary causes of impaired lymphatic flow. Cardiac diseases such as CP, cardiac amyloidosis and pul-

76
monary hypertension are the most common causes of secondary intestinal lymphangiectasia (1). Several reports have described the existence of an association between protein-losing enteropathy and CP (2-4). It has been demonstrated that moderate pericardial constriction not resulting in discernible pressure abnormalities in the right heart can be associated with protein-losing enteropathy and eventually cause hypoproteinemic peripheral edema (4). In our patient, the filling pressures of the right and left ventricles were elevated, and the observed peripheral edema seemed to be the result of the elevated venous pressure and hypoproteinemia.

One of the typical anatomical changes observed in CP is the enlargement of both atria. The LA size and volume index were larger in this patient compared with those reported in age-matched healthy Japanese men (3.6±0.6 cm and 24±9 mL/m², respectively) (5).

Typical hemodynamic changes in patients with CP are often reflected in Doppler echocardiographic findings. In patients with CP, transmitral flow velocity waveforms generally show a pseudonormalized or restrictive pattern that represents impaired LV filling and elevated LV filling pressure. Dissociation of the intracardiac pressure from the intrathoracic pressure and enhanced interdependence between both ventricles are responsible for remarkable changes in transmural and transtricuspid flow velocity waveforms during diastole caused by the respiratory phase. A previous report showed that significant respiratory variations in the peak early diastolic transmitral flow velocity, peak early diastolic transtricuspid flow velocity, and hepatic vein flow velocity had high sensitivities and moderate specificities for the diagnosis of CP (6). The respiratory variations in the peak early diastolic transmitral and peak early diastolic transtricuspid flow velocities observed in this patient met the criteria for the diagnosis of CP. As the LV diastolic property in the longitudinal direction is relatively preserved in patients with CP, as noticed in this patient, the early diastolic mitral annular velocity along the LV long-axis is normal or rather exaggerated (5, 6). This value is useful for distinguishing patients with constrictive pericarditis from those with restrictive cardiomyopathy (7).

Although the LV systolic function is usually preserved in this category of patients, deteriorated LV filling is related to decreases in stroke volume. Little and Freeman (8), in their widely acknowledged review paper, reported that patients with pericardial constriction typically present with manifestations of elevated systemic venous pressure and low cardiac output. Low cardiac output in CP patients is a crucial finding, although most cardiologists may focus more on elevated

---

**Figure 1.** A. A representative image of technetium 99m-labeled human serum albumin-diethylene-triaminepenta-acetic acid (99mTc-HSAD) abdominal scintigraphy. 99mTc-HSAD was found to be accumulated in the intestines in the right side of the abdomen (arrow). Serum albumin was lost into the intestinal lumen. B. Contrast-enhanced cardiac computed tomography. An apparently thickened pericardium and a right-sided pleural effusion were observed. C. Two-dimensional echocardiography. Pericardial thickening around the heart was observed (arrows). D. An apical four-chamber view of the heart at end-systole. The right and left atria were mildly distended.
Calculating intravascular fluid volume caused by hypoproteinemia may have also been related to low stroke volume, which was reflected in the small value of the velocity-time integral at the LV outflow tract measured on pulsed Doppler echocardiography. If a patient shows an inappropriately small value of the velocity-time integral at the LV outflow tract compared with his or her LV systolic function, CP should be considered as a diagnosis.

The authors state that they have no Conflict of Interest (COI).
