Abstract

The patient was a 40-year-old man who had suffered from Crohn’s disease (CD) for 19 years and developed an intractable perianal fistula and two strictures in the small bowel. Dilatation of the two strictures using double-balloon endoscopy did not improve the subileus symptoms. An anal canal adenocarcinoma was also detected using double-balloon endoscopy. The ileum and rectoperianal area were partially resected, and a precise immunohistochemical pathologic assessment revealed that all three lesions were fistula-associated adenocarcinomas. Accumulating endoscopic findings of CD-associated cancer and precise pathologic diagnostic findings will help to establish a suitable surveillance method.

Key words: Crohn’s disease, small bowel adenocarcinoma, double-balloon endoscopy, fistula-associated anal adenocarcinoma, p53

Introduction

Several recent studies have highlighted the risk for the development of colorectal carcinoma and small bowel adenocarcinoma (SBA) in patients with Crohn’s disease (CD) (1-3). These carcinomas, although relatively rare (4), are associated with poor prognoses due to difficulties in diagnosing them preoperatively. In order to facilitate early diagnosis and establish useful surveillance methods, the clinical, endoscopic and pathologic features of many cases must be evaluated and analyzed. We herein describe the endoscopic and precise pathologic findings of a very rare and remarkable case of a patient with CD having two SBAs and a fistula-associated anal adenocarcinoma (FAAA).

Case Report

A 40-year-old man with CD complicated by an intractable anal fistula since 1993 was admitted to our hospital due to subileus symptoms in January 2008. He had undergone omental enteroclysis for a small bowel perforation located 180 cm distal from the ligament of Treitz in October 2005 (Fig. 1). Small bowel enteroclysis showed two strictures (Fig. 2) that were not complicated by any apparent internal fistulae in the proximal or distal ileum. We performed endoscopic balloon dilatation to treat the two strictures with double-balloon endoscopy (DBE) using an oral approach. The first stricture was accompanied by a papillary-protruding lesion (220 cm from the ligament of Treitz; Figs. 1, 3a) and located approximately 40 cm distal from the
Perforation and generalized peritonitis developed suddenly four days before the elective surgery, and the patient underwent emergency partial small bowel resection. The ileum was found to be perforated 200 cm distal from the ligament of Treitz, 20 cm proximal to the first stricture (Fig. 1). Approximately 100 cm of the ileum was resected en bloc from the previously perforated lesion, 20 cm proximal to the present perforation, to 20 cm proximal to the ileocecal valve (Fig. 1). The histopathologic diagnosis of the surgical specimen was a localized well-differentiated adenocarcinoma for the proximal stricture (Figs. 3a, d, 4a, b) and a diffuse and invasive moderately-differentiated adenocarcinoma for the distal stricture (Figs. 3e, 4c-e). A precise pathologic analysis of both lesions revealed that cancer cells lined the inner aspect of the fistula with no marginal dysplasia, and a diffuse Ki-67 expression pattern was observed (the labeling index was 10-50% for the proximal lesion and 50-70% for the distal lesion). In addition, p53 was strongly positive immunohistochemically (Fig. 4f, g). The present case was classified as stage T3N0M0 according to the International Union Against Cancer (UICC)/American Joint Committee on Cancer (AJCC) TNM classification system.

After the patient recovered from the emergency surgery, transanal enucleation surgery was attempted. However, because it was difficult to ensure an adequate view, we performed abdominoperineal resection 2.5 months after the emergency surgery (Fig. 3f). No lymph node involvement was detected in the abdomen. The precise pathologic diag-

nosis was a localized mucinous adenocarcinoma (Fig. 5a-c), and cancer cells lined the inner aspect of the fistula with no marginal dysplasia. The Ki-67 expression pattern was diffuse (the labeling index was 10-60%), and p53 was negative immunohistochemically (Fig. 5d, e). The present case was classified as stage T2N0M0 according to the UICC/AJCC TNM classification system.

We continue to follow this patient, and there has been no evidence of carcinoma recurrence without chemotherapy 42 months after the final surgery.

**Discussion**

Chronic inflammation is widely implicated in neoplastic progression, as represented by colorectal carcinoma-complicated inflammatory bowel disease (1). Colonoscopy is the established method of surveillance for ulcerative colitis-associated colorectal carcinoma. In contrast, surveillance methods for CD-associated SBA and perianal fistula-associated cancer are not yet established because conducting examinations of the deep small bowel insertion is often difficult due to the presence of adhesions. The initial lesions of FAAA in perianal fistulae are usually very difficult to detect using endoscopy, computed tomography or magnetic resonance imaging. Despite the significantly higher relative risk of carcinoma in patients with CD, these lesions are rarely diagnosed preoperatively and have a poor prognosis in the early stages (1-3). In a recent study based on a hospital cohort of 1,935 patients with small bowel-involved CD, the cumulative risk of SBA in the patients with CD (95% confidence interval) was estimated to be 2 (0-8) and 22 (7-64) per 1,000 patients after 10 and 25 years of follow-up, respectively (3). There have been no population-based studies targeting FAAA; however, the presence of anal carcinomas in patients with CD is clearly associated with long-standing perianal fistulae (4, 5). Twenty-three articles describing 59 patients with adenocarcinoma arising from perianal fistulae in patients with CD were reviewed by Igers et al. (6). The overall survival rate following abdominoperineal resection was 88% at one year, 54% at three years and 26% at five years (6). Because a significantly increased cancer risk has been described in patients with rectal remnants (7), abdominoperineal resection should be performed early when permanent fecal diversion is suspected.

We herein described the endoscopic and precise pathologic findings of CD-associated SBA. Patients with CD often have inflammatory strictures of the intestines that are usually not considered malignancies. Because DBE is useful

for diagnosing SBA (8, 9), biopsy specimens should be obtained from small bowel strictures in patients with long-standing CD, especially those refractory to endoscopic balloon dilatation (10). Endoscopic diagnosis of SBA at inflammatory strictures, however, is not yet established in patients with CD. Accumulating endoscopic findings of CD-associated cancer and their precise pathologic diagnostic findings will help to establish suitable surveillance methods. The pathological difference between SBA and FAAA should be evaluated in the near future based on the accumulation of cases including precise pathological diagnoses, as in the present case report. Based on these investigations, early diagnosis of CD-associated cancer, SBA and FAAA, which can be cured by surgery, is an important clinical issue. Furthermore, with the development of anti-tumor necrosis factor agents that provide better prognoses, the establishment of surveillance methods for SBA and FAAA in patients with CD is important to prevent advanced cancer from developing.

The authors state that they have no Conflict of Interest (COI).
