Abstract

We herein report a case of ischemic stroke in a 69-year-old man with unilateral moyamoya vessels originating from the proximal portion of the left middle cerebral artery. In addition, digital-subtraction angiography demonstrated a string-of-beads-like appearance in the cavernous portion of the left internal carotid artery. A genetic analysis revealed a heterozygous c.14576G>A variant in ring finger protein 213. The patient’s younger brother had a history of hemorrhagic stroke and had been diagnosed with moyamoya disease. We finally considered that the unilateral moyamoya vessel and string-of-beads appearance observed in the current case were not simply caused by atherosclerosis, but rather represented symptoms within the moyamoya spectrum.

Key words: moyamoya vessel, RNF213, string-of-beads appearance

Introduction

Moyamoya disease is characterized by the presence of bilateral stenosis or occlusion of the terminal portion of the intracranial internal carotid artery (ICA) or proximal portion of the anterior cerebral artery (ACA) and/or middle cerebral artery (MCA). Abnormal collateral vessels exhibiting a “puff of smoke” appearance (moyamoya vessels) are observed in the vicinity of such arterial lesions (1). The ring finger protein 213 (RNF213) gene was recently identified to indicate susceptibility to moyamoya disease (2). We herein report the case of an elderly man with ischemic stroke and a heterozygous variant of RNF213 who exhibited a unilateral moyamoya vessel and string-of-beads-like appearance in the ipsilateral ICA.

Case Report

A 69-year-old right-handed man was admitted to our hospital with a disturbance of consciousness and right hemiparesis. Before being brought to our hospital, he had been rescued from a fire in his apartment by firefighters. The patient had a history of hypertension, drinking and smoking. He was 167 cm tall and weighed 52.4 kg. Upon admission, his body temperature was 37.6°C, his blood pressure was 170/106 mmHg and his heart rate was 106 beats/min with a regular sinus rhythm. No cardiac murmurs or carotid bruits were audible, and the skin appeared normal. A neurological examination revealed a disturbance of consciousness (Glasgow Coma Scale, 12), motor aphasia, right horizontal gaze palsy, right central facial palsy, dysarthria and right hemiparesis. An extensor plantar response was present on the right side, and the National Institutes of Health Stroke Scale score was 16. The laboratory data showed an elevated blood cell count, with a white blood cell count of 11,440/μL, a hemoglobin level of 17.8 g/dL, and platelet count of 34.1×10^4/μL. The serum blood glucose level was 137 mg/dL, the hemoglobin A1c level was 5.7% and the low-density lipoprotein cholesterol level was 244 mg/dL. In addition, the inter-
and tests for antithrombin, anticardiolipin antibodies, anti-protein C and S levels were also within the normal limits, a free T4 level of 1.13 ng/dL, free T3 level of 2.51 pg/mL 1.9 μg/mL. The patient’s thyroid function was normal, with thromboplastin time was 24.4 s and the D-dimer level was national normalized ratio was 1.12, the activated partial thromboplastin time was 24.4 s and the D-dimer level was 1.9 μg/mL. The patient’s thyroid function was normal, with a free T4 level of 1.13 ng/dL, free T3 level of 2.51 pg/mL and thyroid-stimulating hormone level of 0.85 μU/mL. The protein C and S levels were also within the normal limits, and tests for antithrombin, anticardiolipin antibodies, antinuclear antibodies, anti-DNA antibodies, lupus anticoagulant and anti-β2GPI antibodies were negative. Carotid ultrasonography showed no significant stenosis. The patient was subsequently examined using a 1.5-T magnetic resonance unit (Signa EchoSpeed Horizon, GE Medical Systems, Milwaukee, USA), and diffusion-weighted imaging (DWI) showed hyperintense lesions in the right cerebellum and on the left side of the frontal lobe. Furthermore, occlusion of the left ACA and MCA was seen on magnetic resonance angiography (MRA), and digital-subtraction angiography (DSA) demonstrated collateral vessels, showing a moyamoya vessel originating from the left proximal MCA (Fig. 1). Moreover, DSA revealed dilated lesions in the cavernous portion of the left ICA, representing the so-called “string-of-beads” phenomenon. Although mild, a similar appearance was apparent in the contralateral ICA. Comparable changes were also present in the right posterior cerebral artery; however, no occlusion or similar findings were noted in the contralateral MCA. Transthoracic echocardiography showed stenosis of the middle left ventricle, and computed tomography angiography identified serial calcification of the abdominal aorta. Based on the patient’s advanced age and history of smoking and drinking and the findings of unilateral occlusion and arteriosclerotic changes in the heart and aorta, we initially diagnosed him with ischemic stroke due to ACA occlusion. The etiology of both the MCA and ACA occlusion was considered to be atherosclerosis, although the dilated lesions were atypical.

The family history elicited from his nephew revealed that the patient’s 61-year-old brother had experienced hemorrhagic stroke at 47 years of age; this brother had been injured in the same fire and transferred to another hospital. We subsequently examined him using MRA and identified bilateral ICA occlusion. Interestingly, a dilated appearance was observed in the petrous and cervical portions of the left ICA. In addition, he had been diagnosed with moyamoya disease after DSA performed at 47 years of age revealed moyamoya vessels in the bilateral basal ganglia (Fig. 2).

Based on these findings, we suspected that our elderly patient had developed ischemic-onset quasi-moyamoya disease. After obtaining written informed consent from his legal representatives, a genetic analysis was performed (M.I. and K. H. at Hokkaido University). DNA specimens purified from

Figure 1.  A: Diffusion-weighted imaging shows a hyperintense lesion on the left side of the frontal lobe. B: Digital-subtraction angiography (DSA) demonstrates moyamoya vessels (arrow) originating from the proximal portion of the left middle cerebral artery. C: Repeated dilated lesions (arrow) are observed in the cavernous segment of the left internal carotid artery. D: Three-dimensional DSA of the dilated lesions. E: No occlusion is present in the contralateral middle cerebral artery. F: Dilated lesions are also seen in the right internal carotid artery (arrow) and posterior cerebral artery (arrow-head).
the patient’s blood samples revealed the c.14576G>A heterozygous variant in RNF213 (Fig. 3). As a result, we finally considered that the unilateral moyamoya vessel and string-of-beads appearance noted in this case were not simply caused by atherosclerosis, but rather represented symptoms of the moyamoya spectrum.

**Discussion**

We herein reported a case of ischemic stroke associated with heterozygous c.14576G>A polymorphism in RNF213 in which the patient displayed a unilateral moyamoya vessel and a dilated lesion showing a string-of-beads appearance in the ICA.

The patient in this case had several risk factors for atherosclerosis, including an advanced age and history of hypertension, smoking and drinking. In addition, systematic atherosclerotic changes were seen in the heart and abdominal aorta. Atherosclerosis is a well-known differential diagnosis of moyamoya disease (1). Atherosclerotic risk factors have previously been reported to be more frequent in patients with unilateral moyamoya vessels than in those with moyamoya disease (3). Although some cases of unilateral moyamoya vessels progress to the bilateral form, this phenomenon is primarily observed within 1-2 years in childhood. The possibility of progression in adolescence and beyond appears to be infrequent (4, 5). The level of basic fibroblast growth factor in the cerebrospinal fluid is reported to be related to progression (6). It thus is reasonable to consider that the presence of unilateral moyamoya vessels in elderly individuals is attributable to atherosclerosis and that this phenomenon is distinct from moyamoya disease.

The present elderly patient with a unilateral moyamoya vessel had a family history of moyamoya disease. In addition, a genetic analysis revealed the presence of the risk allele in RNF213. Liu et al. identified RNF213 as a susceptibility gene for moyamoya disease, showing that a knockdown zebrafish model results in the formation of vessels with an irregular diameter that exhibit aberrant sprouting (2). In a recent study by Miyawaki et al., over 80% of moyamoya disease patients were found to have the variant RNF213, (7) although no significant associations with extracranial carotid atherosclerosis, cerebral aneurysm development or intracerebral hemorrhage were identified. Intriguingly, the authors also reported that 22% of patients with unilateral ICA occlusion or stenosis display the variant RNF213. Patients diagnosed with the uni- or bilateral form of the condition may not necessarily present with the pathogenesis of moyamoya disease. Current guidelines do not confirm the present case to be moyamoya disease due to the presence of unilateral occlusion. However, we believe that genetic analyses of RNF213 provide a key to understanding the etiology of the disease, even in elderly patients with unilateral moyamoya vessels and siblings who present with definitive moyamoya disease.

In the current case, a dilated lesion with a string-of-beads appearance was observed in the cavernous segment of the ICA. Although the severity of the condition differed, his younger brother also exhibited dilated lesions in the ICA. These findings are not in line with the pathological consensus that moyamoya disease involves the presence of occlu-
sion or stenosis in the terminal portion of the ICA (8). However, several case reports have described dilated lesions. For example, Khan et al. reported the cases of two unrelated children with moyamoya disease who showed bilateral dolichoectatic ICA lesions. Both patients also presented with pupillary dysfunction and cardiac malformations (9). Cases of moyamoya vessels originating from dolichoectatic arteries have also been reported (10, 11). Although genetic abnormalities, infection, environmental factors, cytokines and autoimmune mechanisms are all presumed to be associated with the pathogenesis of moyamoya disease, the etiology of this disorder has yet to be fully elucidated. We presume that the similarity in dilated appearance between our patient and previously reported cases indicates the presence of an unknown factor that organizes dilated lesions in patients with moyamoya disease.

In conclusion, the present report suggests that some cases of unilateral moyamoya vessels fall within the spectrum of moyamoya disease, even if the patient exhibits several atherosclerotic risk factors and dilated lesions.

The authors state that they have no Conflict of Interest (COI).
