CASE REPORT

Acute Myocardial Infarction due to Left Atrial Myxoma

Abstract

Myxoma is a common benign cardiac tumor that may rarely cause an acute myocardial infarction. A 77-year-old woman was admitted to our hospital with chest pain. Electrocardiography showed an ST elevation in leads V₃₋₆. Transthoracic echocardiography revealed an ovoid mass with fragmentation in the left atrium and hypokinesia of the left ventricular apex. Coronary angiography indicated the presence of a coronary embolism that was suspected to be from the left atrial mass. The mass was removed by emergency surgical resection to avoid a further systemic embolism and was diagnosed pathologically as a myxoma. The patient was discharged after 13 days with no complications.

Key words: myocardial infarction, myxoma

Introduction

Myxoma, a rare condition, is the most common type of primary cardiac tumor, and accounts for half of all cases of benign cardiac tumors (1). Despite its benign pathologic nature, catastrophic results can occur as a result of systemic embolism, including myocardial infarction. In this report, we describe a case of acute myocardial infarction caused by coronary embolism that was suspected to be due to a left atrial (LA) myxoma.

Case Report

A 77-year-old woman without any coronary risk factors other than hypertension was admitted to the emergency department of our hospital with chest pain. She had not previously noticed any chest pain or dyspnea on exertion; however, her body weight had decreased by 3 kg in three months. On physical examination, the patient’s blood pressure was 152/97 mmHg, her heart rate was 84 beats/min, her oxygen saturation was 95% with room air, her respiratory rate was 12 breaths/min, and her body temperature was 36.7°C. Auscultation revealed a systolic murmur (Levine 2/6) at the level of the third left intercostal space and no lung rales; moreover, no rashes or lymphadenopathy were noted. Her cardiothoracic ratio, measured on a chest X-ray, was 60%. An electrocardiogram showed ST elevation in leads V₃₋₆ (Fig. 1). The laboratory findings included a cardiac troponin I level of 3.31 ng/mL, a creatine kinase (CK) level of 210 U/L, and a CK-MB level of 20.9 U/L. The patient’s white blood cell count was 4,610/μL and her D-dimer level was 3.4 μg/mL. Moreover, her C reactive protein level was 1.3 mg/mL, her erythrocyte sedimentation rate was 87 mm/h, and her B-type natriuretic peptide level was 30.1 pg/mL.

A transthoracic echocardiographic (TTE) examination showed a left ventricular diastolic diameter of 42 mm, a systolic diameter of 28 mm, and an ejection fraction of 61%. The LA was dilated (LA diameter: 36 mm, LA volume index: 37 mL/m²), although the mitral inflow pattern was consistent with the patient’s age (E wave peak: 70 cm/s; A wave peak: 102 cm/s; E deceleration time: 248 ms). Hypokinesia of the left ventricular apex was noted. The TTE examination also revealed a mobile mass in the LA, although there was no evidence to suggest it was obstructing the mitral valve (Fig. 2).

Because acute anterior myocardial infarction was suspected, we performed emergency coronary angiography (CAG). CAG indicated the sub-total occlusion of the distal left anterior descending artery (LAD), which was suspected to be due to an embolism from the left atrial mass (Fig. 3). In addition, CAG indicated the presence of feeding arteries toward the LA mass from the right coronary artery (RCA) (Fig. 4). The LA mass was swinging in the heart chambers during the cardiac cycle. Percutaneous coronary interventions, such as aspiration for coronary embolism, were not performed because the culprit lesion was too distal.

Right heart catheterization revealed that the patient’s hemodynamic status was within normal limits. After CAG, transesophageal echocardiography (TEE) was performed, which showed a mobile mass, measuring 31×27 mm, with an irregular and fernlike surface and an inhomogeneous appearance (arrow) (Fig. 5). The mass was widely attached to the interatrial septum between the fossa ovalis and the mitral valve. Color Doppler signals were detected in the mass. Cardiac magnetic resonance imaging (MRI) demonstrated that the mass originated in the left atrium. The signal intensity of the mass was similar to that of the myocardium on T1-weighted images, and high on T2-weighted images, along

with enhancement on gadolinium-enhanced images (Fig. 6). These findings on cardiac MRI are typical findings for myxoma. Moreover, MRI of the head detected a small cerebral infarction, while both kidney and spleen infarctions were detected by enhanced computed tomography (Fig. 7).

Emergency surgical resection of the villous mass was performed to avoid further systemic embolism. The histopathological examination of the left atrial mass determined that it was a myxoma, and also demonstrated the presence of bleeding (Fig. 9). 99m-Technetium pharmacological stress myocardial perfusion imaging showed no defect on either the stress or the rest image after surgery (Fig. 10). There were no complications in the postoperative period. A TTE examination performed one week after surgery, showed an ejection fraction of 66% without asynergy. The patient was discharged after 13 days.

**Discussion**

Primary cardiac tumors are rare, with a frequency of only 0.0017-0.033% in autopsy cases (2). Myocardial infarction due to myxoma is also extremely rare. None of the 74 cases of coronary emboli analyzed in a retrospective autopsy study was due to a myxoma (3). The incidence of coronary embolization due to cardiac myxoma is reported to be only 0.06% (4). According to a review of 40 cases of coronary artery embolization secondary to atrial myxoma, the patients’ mean age was approximately 50 years, the RCA was a common culprit, and inferior myocardial infarction was seen in most cases (5). Panos et al. investigated the lesions and culprit arteries of myocardial infarctions due to cardiac myxomas that were diagnosed by echocardiography (6).
their report, inferior myocardial infarctions were seen in
63.3%, anterior infarctions were noted in 22.7%, and poste-
rior infarctions were observed in 9.1% of the cases. CAG
showed RCA embolization in 47.6% of the patients with
embolism, and the investigators speculated that the reason
for this high frequency was the anatomical position of the
RCA ostium in relation to the aortic blood flow (6). They
also reported that 23.8% of the cases had a normal angi-
ogram. Braun et al. noted that the coronary artery may still
appear to be normal, despite a clinical diagnosis of acute
embolic myocardial infarction, because of the myxomatous
histology of the tumor, which allows it to embolize and re-
solve spontaneously (5). Ibrahim et al. reviewed 17 cases of
myocardial infarction due to LA myxoma from 2003 to
2013 (7). According to the review, 10 case reports showed
no evidence of myocardial infarction on CAG. Our patient
was diagnosed with myocardial arterial embolism in the
LAD, as detected by CAG. We considered our case to in-
volve acute LAD myocardial infarction due to embolization
from the myxoma, based on the CAG and echocardiography
findings and the absence of any other atherosclerotic risk
factors (with the exception of hypertension).

Systemic embolism due to atrial myxoma is frequently
noted in the clinical setting; in one study, this condition oc-
curred in 32% of cases as the presenting symptom (8).
However, the incidence of coronary embolization due to
atrial myxoma is only 0.06%. Lehrman et al. suggested that
a possible explanation for this low incidence could involve
the right-angled junction of the coronary apertures within
the aortic root, the protection of the coronary arteries by the
aortic valve cusps, the small diameter of the apertures, and the filling of the coronary arteries during ventricular diastole (4). Although less common, myxoma has been reported to cause death from coronary embolization (9). Thus, it is clinically important to identify the patients who are at a high risk of systemic embolism caused by cardiac myxoma.

The early detection of cardiac myxoma and the assessment of the risk of systemic embolism are important for the prevention of serious complications, including fatal myocardial infarction. Echocardiography is widely available and is often utilized as a diagnostic test in patients with a typical symptom of myxoma. Two different anatomic types of myxoma have been determined through echocardiography: round, which is solid and has a round shape with a non-mobile surface; and polypoid, which is soft and has an irregular shape with a mobile surface (10). The incidence of systemic embolism is higher in tumors with an irregular and friable surface than in those with a smooth surface (11). Ha et al. showed that prolapsing and polypoid tumors were associated with embolism (10). The more irregular and friable the myxomas, the higher the likelihood of embolism. Another study reported that the incidence of neurologic symptoms and brain infarctions was significantly higher for papillary-type myxoma, which is soft and has an irregular shape, than for the ovoid type myxoma, which is solid and has a smooth surface (12). In our patient, the appearance of the tumor was irregular; it had a mobile surface with fragmentations, which indicated a high risk of systemic embolization. Hence, emergent surgical resection was subsequently performed.

Echocardiography should be performed in detail as soon as possible to guide the management of patients with cardiac myxoma. Although most LA myxomas are attached to the LA septum, Swartz et al. reported that an extraseptal location was correlated with embolic events (13). It is also useful to assess the risk of embolism with findings on CAG. Shimono et al. found that clusters of tortuous tumor vessels on CAG may predict a solid type tumor (14). On the other hand, a lack of tortuous vessels was identified in papillary-type myxomas. In our patient, given that contrast medium pooling was only identified by CAG in the feeding artery, the myxoma was judged to be of the papillary type, with a high risk of embolization.

Our patient had lost weight, which is considered to be one of the constitutional symptoms of myxoma. It is reported that constitutional symptoms are mediated through increased interleukin-6 (IL-6) release from myxoma cells (15). In the present case, the preoperative IL-6 level was 10.77 pg/mL. Wada et al. reported a case of cardiac myxoma that metastasized to the brain and suggested that IL-6 might possibly potentiate metastasis of a cardiac myxoma (16). Therefore, our myxoma patients might be at a higher risk of coronary embolism. Moreover, the progression of myocardial ischemia is possible due to the metastasis of a myxoma to a coronary artery. In such cases it is important to assess the progression of myocardial ischemia with coronary computed tomography, myocardial perfusion imaging, or coronary angiography, in addition to performing echocardiography at periodic intervals after the resection of the tumor.

We herein reported an interesting case of myocardial infarction due to coronary embolization. Coronary embolization secondary to atrial myxoma is rare. In this case, the embolization was judged to be due to the presence of an

Figure 10. Technetium pharmacological stress myocardial perfusion imaging showed no defect on either the stress or the rest image after surgery.
atrial myxoma, based on the findings of CAG and echocardiography. Thus, it is important to assess the risk of systemic embolization as soon as possible when an atrial myxoma is identified, in order to guide the effective management of such patients.

The authors state that they have no Conflict of Interest (COI).
