Abstract

Although high-quality cardiopulmonary resuscitation (CPR) is essential for survival from cardiac arrest, chest compressions can also sometimes lead to life-threatening chest injuries. In addition, post-cardiac arrest syndrome patients often have coagulopathy due to therapeutic hypothermia, mechanical hemodynamic support, or both. Therefore, when progressive anemia and prolonged shock are detected in patients who have received CPR, identifying the cause of hemorrhagic shock is crucial. We herein present an interesting case of hemorrhagic shock due to an internal mammary artery injury secondary to CPR that was detected by computed tomography and invasive angiography.

Key words: internal mammary artery injury, cardiopulmonary resuscitation, post-cardiac arrest syndrome

Introduction

The 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care emphasize high-quality cardiopulmonary resuscitation (CPR) as the cornerstone for survival from cardiac arrest. While the 2005 guidelines recommended compressions to a depth of 38 to 50 mm, the 2010 guidelines recommend a depth of ≥50 mm with no upper limit specified (1, 2). However, there is an increased risk of complications with the deeper compressions recommended by this new guideline (3). Several studies have shown that computed tomography (CT) can be useful for detecting various chest injuries arising as complications associated with CPR (4-6). In the emergency department, identifying the presence of active bleeding is one of most important steps in the management of acute trauma. Contrast enhanced CT can detect sites of active bleeding when a patient is in hemorrhagic shock. It is also useful for deciding between surgical or radiological intervention for achieving hemostasis.

We herein present a case of hemorrhagic shock caused by an internal mammary artery (IMA) injury related to CPR that was detected by CT and invasive angiography.

Case Report

A 77-year-old man with a mechanical mitral valve and left ventricular dysfunction (left ventricular ejection fraction, 39%) was transferred to our emergency department due to sustained ventricular fibrillation (VF) for at least 33 minutes despite undergoing continuous CPR that included manual chest compressions and electrical defibrillation by emergency medical service personnel.

On admission, since the intravenous administration of amiodarone was ineffective in terminating VF, arteriovenous bypass via venoarterial extracorporeal membrane oxygenation (VA-ECMO) was quickly introduced (door to ECMO time, 23 minutes). The VA-ECMO flow was established with right femoral venous cannulae for withdrawing deoxy-
Despite the transfusion of red blood cells, platelets, and frozen fresh plasma, his vital signs remained unstable and coagulopathy persisted. Chest radiography showed a larger mediastinal silhouette (Fig. 1C). Therefore, we performed contrast enhanced CT. Contrast material was administered as a bolus of 79 mL at 2.6 mL per second via a right jugular venous catheter. CT at 70 seconds after contrast administration revealed additional retrosternal hemorrhaging with contrast material extravasation and hemothorax (Fig. 1D, 2); therefore, we suspected an injury to the left IMA. Selective transcatheter angiography demonstrated extravasation from a branch of the left IMA (Fig. 3). Selective transcatheter arterial embolization with Spongell® cut-off gelatin sponges (Astellas Pharma, Tokyo, Japan) was performed. After achieving hemostasis, the patient’s anemia improved immediately and his hemodynamic parameters stabilized. ECMO and IABP were successfully weaned on hospital days 3 and 4, respectively. The patient was discharged from our hospital and transferred to a rehabilitation clinic on day 61. His cerebral performance category upon discharge from our hospital was 3.

### Discussion

IMA injury secondary to blunt chest trauma is a rare en-
Figure 2. Bleeding from a left internal mammary artery injury on reconstructed 3-dimensional computed tomography images. Three-dimensional contrast enhanced CT showed contrast media extravasation (yellow arrows) close to the left internal mammary artery (yellow arrowheads). The location of the sternal fracture is indicated by a white arrowhead. Left anterior oblique views are shown in (A) and (B). (C) and (D) are left posterior oblique views. (A) and (C) are merged with bone images. CT indicates computed tomography.

The presence of an anterior mediastinal hematoma implies IMA injury, a mediastinal hematoma secondary to blunt chest trauma can be due to injuries of other vessels including the aortic arch, intercostal, internal thoracic, and small mediastinal vessels and rib or sternum fractures (7). Thoracotomy and endovascular intervention are therapeutic options for IMA injury. In a review article of 49 patients with IMA injury due to blunt chest trauma, 22 patients (45%) underwent surgery and 20 patients (41%) underwent transcatheter embolization (9). The possible mechanisms of IMA injury include a fracture of an adjacent bony structure, such as a rib, clavicle, or sternum or shearing forces acting on the vessel during extreme acceleration or deceleration (10). Although there are no clinical studies of IMA injury related to CPR, the incidence of IMA injury related to CPR, the incidence of mediastinal hematoma due to chest compressions with a depth of 4 to 5 cm is reported to be 10% (11). In this particular patient with postoperative adhesions between intrathoracic blood vessels, sustained chest compressions may have led to IMA injury. In addition, coagulopathy secondary to post-cardiac arrest syndrome (PCAS), therapeutic hypothermia, anticoagulation for the mechanical heart valve, and mechanical circulatory support are precipitating factors for hemorrhage.

In this case, contrast enhanced CT was useful for detecting CPR-related IMA injury. CT is rapidly becoming the standard modality for assessing cardiovascular disorders such as aortic dissection (12) and pulmonary embolus (13) due to its greater spatial and temporal resolution. In brief CT angiography is usually recommended for assessing active arterial extravasation in the presence of vascular injury. Since the presence of a mediastinal hematoma and its anatomical location suggested a vascular origin, CT can be useful for distinguishing between angiographic and surgical intervention (9, 14, 15). However, in patients with specific hemodynamic changes due to severely impaired left ventricular function and mechanical circulatory support, it can be difficult to optimize contrast enhancement and diagnostic imaging quality. In patients on VA-ECMO, injecting contrast into a blood vessel in an extremity is not recommended due

to insufficient circulation (16). When performing CT angiography to detect vascular injuries in patients with PCAS on mechanical circulatory support, contrast medium should be administrated via a central vein in the upper body and several scans should then be performed to determine the suitable contrast conditions for obtaining high-resolution images. Indeed, in this case, we re-scanned at 70 seconds after contrast injection to assess extravasation behind the sternum because images at 30 seconds after bolus injection through the right jugular vein were inadequate for detecting extravasation.

Although high-quality CPR is essential for survival from cardiac arrest, chest compressions can lead to life-threatening chest injuries. Since patients with PCAS have a high risk of bleeding, especially those undergoing mechanical circulatory support or therapeutic hypothermia, the occurrence of retrosternal hemorrhaging due to IMA injury should be considered in PCAS patients with anemia refractory to transfusion.

The authors state that they have no Conflict of Interest (COI).
