LETTERS TO THE EDITOR

Autoimmune Hemolytic Anemia Induced by Adalimumab

Key words: adalimumab, anti-tumor necrosis factor agents, autoimmune hemolytic anemia, rheumatoid arthritis, psoriasis

To the Editor We read with great interest the recent article by Harada et al. titled “Autoimmune Hemolytic Anemia During Adalimumab Treatment for Plaque Psoriasis”, which reported that autoimmune hemolytic anemia (AIHA) might be induced in a patient with psoriasis by long-term adalimumab treatment (1). However, we disagree with their conclusion.

Their patient developed AIHA after treatment with adalimumab for 3 years (1), however, a 3-year exposure period is quite unusual for drug-induced adverse events. Anti-tumor necrosis factor (TNF) agents are well known to induce autoimmune phenomena, including vasculitis, systemic lupus erythematosus (SLE), and psoriasis. The mean duration of exposure was reported to be 38 weeks for vasculitis and 41 weeks for SLE (2), and the median exposure time was reportedly 6 months for psoriasis (3). Hematological complications of anti-TNF agents are rare (4). With regard to thrombocytopenia and neutropenia associated with anti-TNF agents, the reported exposure time has ranged from 1 to 67 weeks and 2 to 56 weeks, respectively (4). Harada et al. cited three reports concerning the induction of AIHA by monoclonal antibodies (1). In two of the three reports, there is at least chronological plausibility, since AIHA was induced after 6 and 8 months of treatment. The remaining article reported an experimental study on the toxicity of an anti-HM1.24 monoclonal antibody; AIHA was induced after one month of repeatedly administering a toxic dose of this antibody to monkeys.

Harada et al. suggested that the mechanism of hemolytic anemia was related to the formation of complexes between adalimumab and “anti-adalimumab antibody” on erythrocytes, which stimulate the immune system to produce anti-erythrocyte antibodies. However, this mechanism was derived from the above-mentioned animal toxicity study of anti-HM1.24 antibody and it may not apply to the present patient.

Drug-induced immune hemolytic anemia is very rare (5). It has mainly been reported with antibiotics, followed by nonsteroidal anti-inflammatory drugs, antineoplastic agents, and antihypertensives/diuretics. Hemolytic anemia induced by cephalosporins occurs soon after the start of treatment, with a mean duration until onset of 9 and 12 days for cefotetan- and ceftriaxone-induced hemolytic anemia, respectively. Garratty suggested that if patients with AIHA have anti-erythrocyte antibodies, then idiopathic warm-type AIHA should be primarily considered because it is much more common than drug-induced immune hemolytic anemia and the drug history may be a “red herring” (5).

While it is important for clinicians to report uncommon drug-induced adverse events, the causality must be assessed carefully.

The authors state that they have no Conflict of Interest (COI).
