Abstract:
We herein report a rare case of oral mucormycosis following allogeneic hematopoietic stem cell transplantation. Oral mucormycosis due to Rhizopus microsporus manifested as localized left buccal mucositis with a 1-cm black focus before neutrophil recovery. Combination therapy with liposomal amphotericin B was initiated and surgical debridement was performed; however, the patient died due to progressive generalized mucormycosis. Considerable attention needs to be paid to the diagnosis and management of oral mucormycosis in post-transplant patients, thereby suggesting the importance of fully understanding the risk factors.

Key words: oral mucormycosis, allogeneic hematopoietic stem cell transplantation, acute myeloid leukemia

Introduction

Mucormycosis is a rare infectious complication with an incidence of 0.6% among patients who received allogeneic hematopoietic stem cell transplantation (allo-HSCT) (1). Mucormycosis as a breakthrough infection appears to have increased among patients with hematological diseases because of the use of anti-aspergillus azoles or echinocandins as routine prophylaxis (2). Mucormycosis typically presents as an acute, aggressive, and frequently angio-invasive mold infection, and it is often a life-threatening opportunistic infection after allo-HSCT (1). The risk factors for mucormycosis include poorly controlled diabetes mellitus, iron overload, a previous history of iron-chelating therapy, the development of graft-versus-host disease, prolonged neutropenia, and systemic corticosteroid administration (3-5). However, no risk-stratified therapeutic modality has yet been established. Therefore, mucormycosis needs to be diagnosed at an early stage. Based on previous findings showing the successful outcomes of complete surgical debridement together with liposomal amphotericin B (L-AMB) (4, 6, 7), an early diagnosis of oral mucormycosis appears to be advantageous for minimizing the amount of tissue that needs to be removed.

Mucormycosis manifests in 6 predominant clinical forms: rhino-cerebral, pulmonary, cutaneous, gastrointestinal, disseminated, and miscellaneous, including oral (3). Pulmonary lesions are a common manifestation in patients with hematological diseases including post-transplant patients (4); however, manifestations other than the pulmonary form are very rare. Oral mucormycosis has been reported to also develop in immunocompromized patients, such as those with poorly

controlled diabetes mellitus, and *Rhizopus oryzae* is the most frequent pathogen. (4, 8). But it is unclear whether the clinical manifestation of oral mucormycosis differs according to the type of the pathogen. In this article, we describe a rare case of oral mucormycosis caused by *Rhizopus microsporus* in post-transplant patients.

**Case Report**

A 56-year-old male was diagnosed with secondary acute myeloid leukemia (AML) which had transformed from polycythemia vera in September, 2009. The laboratory findings were as follows: white blood cell count, 54.8×10^3/L with 37% myeloblasts and 49% neutrophils; hemoglobin level, 15.0 g/dL; platelet count, 502×10^3/L. The patient had no apparent underlying complications, potential infectious diseases or any specific opportunity of environment, including his occupation, exposure to *Mucor* species (e.g., decaying vegetation and soil, barns, compost piles, plants, and smoking), and had not been administered voriconazole or iron chelators. Standard chemotheraphy with cytarabine and daunorubicin did not result in hematological remission. The patient was isolated in a laminar air flow room from the initiation of induction treatment. Therapy with low-dose cytarabine was subsequently administered to debulk AML blasts before allo-HSCT. The patient’s general condition was maintained without any infectious diseases or oral mucositis despite prolonged severe neutropenia. The patient did not have any donor candidates among his siblings or in the Japan Marrow Donor Program. After receiving one course of low-dose cytarabine, unrelated cord blood transplantation (total nucleated cell dose, 4.28×10^7 cells/kg; CD34-positive cell dose, 0.62×10^4 cells/kg; HLA 4/6 loci mismatched, from a male donor) was performed using myeloablative conditioning (fludarabine 120 mg/m², intravenous busulfan 12.8 mg/m², and total body irradiation 4 Gy / 2 fr.) in October 2010. Tacrolimus and oral mycophenolate mofetil were used as agents for graft-versus-host disease (GVHD) prophylaxis. Micafungin at 50 mg daily and levofloxacin at 500 mg daily were administered for anti-fungal and -bacterial prophylaxis, respectively.

On day +6 of transplantation, the patient developed fever with grade 3 oral mucositis during persistent severe neutropenia. According to the c-D-index, the scoring system to with grade 3 oral mucositis during persistent severe neutropenia. According to the c-D-index, the scoring system to come. Mucormycosis mostly involves pulmonary or rhino-encephalitis progressing rapidly despite treatments with 5 different antibiotics, and his general condition deteriorated (Fig. 1A and B). Computed tomography revealed edematous changes in the larynx and pharynx, and subcutaneous swelling from the left cheek to the neck (Fig. 1C and D). Oral mucormycosis was clinically diagnosed based on the clear boundary of necrotic tissue with an obstructed airway. A skin biopsy on day +24 showed that the necrotic surface layer was covered with non-septate hyphae with branching at wide angles (Fig. 2A-C). Fungal cultures revealed broad hyphae with very few septa that produced long sporangiospores terminating with a dark and round sporangium (Fig. 2D). A molecular analysis using a polymerase chain reaction method identified *Rhizopus microsporus* as follows; DNA was extracted from fungi cultured in Sabouraud agar using a nucleic acid extraction kit (Kyokuto Pharmaceutical Industrial, Tokyo, Japan). Next, using the extracted DNA as a template, PCR was carried out with the fungal D1/D2 region as a target using a kit [Fungal rDNA (D1/D2) PCR kit fast, Takara, Kusatsu, Japan] (http://www.clontech.com/JP/Products/PCR/Pathogen_Detection_and_Screening_Kits/Bacteri al_Pathogen_Detection/rDNA_PCR_Kits?sitex=10025:2237 2-US), as previously described (10). The PCR amplification product of approximately 650 bps was purified and labeled, and the nucleotide sequence was determined by direct sequencing (Genetic Analyzer 3130, Applied Biosoys, Tokyo, Japan). Based on the obtained nucleotide sequence, the homology of the nucleotide sequence was analyzed using a database (BLAST), and the one having the highest homology was used to identify the fungal species.

The administration of 5 mg/kg/day L-AMB was initiated and surgical debridement was performed on day +24, as described previously (4, 6, 7). However, debridement could not be completed due to the presence of a large necrotic lesion involving the floor of the mouth, tongue, and mandible. The patient was treated with L-AMB for 7 days, but died on day +31 after allo-HSCT (Fig. 3).

**Discussion**

Oral mucormycosis in this patient occurred before neutrophil engraftment after transplantation, rapidly progressed despite combination therapy with the administration of L-AMB and surgical debridement, and resulted in a fatal outcome. Mucormycosis mostly involves pulmonary or rhinocerebral lesions at the late phase after allo-HSCT (3-5), while oral mucormycosis is more likely to occur before neutrophil recovery (11-14). The clinical course of this case indicated the important risk factors for oral mucormycosis after allo-HSCT.

This case had sustained neutropenia, even before undergoing allo-HSCT, which may have been related to refractory AML itself and chemotherapy until shortly before HSCT. The prolonged neutropenic period before and after HSCT (high c-D-index on day +6 of allo-HSCT) may have had an unfavorable influence on mucormycosis. Although the D-index and c-D-index were originally established to estimate
Figure 1. Skin appearance and computed tomography findings of oral mucormycosis. A black necrotic area progressively enlarged on day+15 (A) and day+24 (B) after transplantation. Computed tomography showed swelling of the oral mucosa and lower jaw skin that rapidly progressed on day+18 (C) and day+20 (D).

Figure 2. Pathological findings and a tissue culture of oral mucormycosis. A skin biopsy specimen was completely necrotic, with a surface that was covered by non-septate hyphae with branching at wide angles [Hematoxylin and Eosin (H&E) staining, 100x] (A). Hyphae infiltrated the vessels and surrounding subcutaneous tissue (H&E staining, 200x) (B). Grocott’s methenamine silver stain revealed the presence of fungal hyphae (400x) (C). A skin culture grew Mucor spp. (D).
the risk of mold infection, mainly aspergillosis, these indexes might be also useful for predicting the risk of mucormycosis, which was calculated including the neutropenic period before and after transplantation. Considering the serious clinical course of mucormycosis, it is necessary to establish either a scoring system for its prediction or a risk assessment system using a large cohort of patients under severe immune suppression, such as those with prolonged neutropenia, and those after transplantation.

Oral mucositis in the present case may have been closely related to the development of oral mucormycosis. Mucosal toxicity appeared to have been enhanced by cytotoxic chemotherapy before the conditioning regimen, and conditioning with radiation severely aggravated it, thus increasing the risk of invasive oral infection.

Furthermore, the prolonged use of Micafungin from before transplantation also promoted the development of oral mucormycosis through selective pressure on molds (15, 16). Based on the efficacy of L-AMB for patients with febrile neutropenia (17), its administration represents an important therapeutic option as an initial empirical therapy when patients have a condition similar to that observed in the present case. Because there is a report demonstrating that Rhizopus microporus was less sensitive to posaconazole than other Mucor species in vitro (18), the use of L-AMB as an initial empirical therapy should thus be considered for patients suspected of having oral mucormycosis.

The early application of combination therapy with complete surgical debridement and L-AMB administration has been reported to be successful in some cases with oral mucormycosis (12, 13). Surgical debridement was performed and the administration of L-AMB was also initiated for the present case, but these treatments failed to successfully treat the disease. Due to the limitations associated with the diagnostic modality used to detect mucormycosis at an early phase, the development of novel methods is required for severely neutropenic patients. Recent studies reported that a quantitative polymerase chain reaction (PCR) for the detection of circulating DNA using serum samples is effective for diagnosing mucormycosis at an early stage (19, 20), and a novel antigen specific to Rhizopus species was identified using an animal model (21). A preemptive strategy for mucormycosis using L-AMB guided by a PCR method and antigen detection to identify invasive aspergillosis using the galactomannan test may thus be warranted in the future (22, 23).

In conclusion, considerable attention needs to be paid to the diagnosis and management of oral mucormycosis in
post-transplant patients with the following risk factors: (i) persistent neutropenia before and after transplantation, (ii) the potential risk of oral mucositis by cytotoxic treatments before the initiation of a conditioning regimen, and (iii) the use of azole or echinocandin as prophylaxis. In the present practice, performing combination therapy with complete surgical debridement and the administration of L-AMB should be applied as early as possible when mucositis with a small necrotic area develops in patients with such risk factors.
