Abstract:
We herein report the first case in which an escalated dose of sunitinib was effective, even after dose reduction. A 64-year-old man with gastrointestinal stromal tumor of the small intestine discontinued adjuvant imatinib because of interstitial pneumonia. After two years, peritoneal recurrence was detected. Sunitinib was started at 50 mg/day for 4 weeks every 6 weeks, after which the dosage was reduced to 37.5 mg/day because of grade 1 gastritis, stomatitis, and a fever. Four months later, computed tomography showed progressive disease. As the adverse events were well-controlled by medication, we escalated the dose to 50 mg/day and achieved a partial response.

Key words: gastrointestinal stromal tumor, sunitinib, dose modification

Introduction
Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of the gastrointestinal tract. Surgical resection is the first recommended therapy, and systemic chemotherapy is administered for unresectable tumors, as they are resistant to radiotherapy. However, conventional chemotherapies are not applicable, and tyrosine kinase inhibitors (TKIs) show efficacy on GISTs according to the tumor molecular pathogenesis.

Imatinib mesylate, a small molecule that inhibits the activation of KIT and platelet-derived growth factor receptor (PDGFR)α proteins, is the first choice of treatment for GISTs (1, 2). Sunitinib has significant clinical benefits in patients with imatinib-resistant GISTs. It is approved at a dose of 50 mg/day for 4 weeks followed by a 2-week off period (2, 3), but in a clinical setting, it is usually intolerable due to adverse events. Therefore, dose modification is usually required.

We herein report the first case in which escalating the dose of sunitinib was effective, even after dose reduction. We also show the effectiveness of modifying the sunitinib-administration schedule.

Case Report
A 64-year-old man visited our hospital with complaints of anorectal pain and incomplete stool evacuation. Computed tomography (CT) and magnetic resonance imaging showed a mass in the left lower quadrant of the abdomen (Fig. 1). As colonoscopy revealed no lesions, a submucosal tumor was suspected. Laparotomy was performed for diagnostic treatment, and the tumor turned out to be a 7.5-cm GIST of the small intestine with a mitotic rate of 23 mitoses per 50 high-power fields (HPF). It harbored a mutation in KIT exon 11 (Fig. 2). The tumor was classified as having a high risk of recurrence using the modified-Fletcher classification, and adjuvant therapy with imatinib was planned. Due to interstitial pneumonia, imatinib was discontinued after eight...
months of administration.

After a treatment-free period of about two years, peritoneal recurrence was detected (Fig. 3). This time, sunitinib at 50 mg/day was introduced because imatinib was intolerable due to interstitial pneumonia. However, grade 1 gastritis, grade 1 stomatitis, and a grade 1 fever were subsequently observed, leading to a dose reduction to 37.5 mg/day. A schedule of 4 weeks on and 2 weeks off with 37.5 mg resulted in a partial response after approximately two months. Concurrently, varicella zoster virus infection occurred. He also suffered peripheral nerve disorder. As we realized that the dose intensity could not be maintained by the current approach of drug administration, the sunitinib schedule was modified to two weeks on and one week off.

After two months, CT showed disease progression. Changing the drug to regorafenib was a reasonable choice, but sunitinib escalation was also feasible, as the adverse events were not observed at that time. In fact, prophylaxis against gastritis, stomatitis, and hand-foot syndrome was effective. As the patient did not want to change to another drug, the dose of sunitinib was escalated to 50 mg/day for 2 weeks followed by 1 week off. This time, the patient exhibited a partial response (Fig. 4). The patient has continued sunitinib for 20 months now, and the tumor remains small, although dose reduction to 25 mg/day was required because of grade 3 hypertension and grade 2 edema (Fig. 5, 6).

**Discussion**

We experienced a case, in which an escalation in the dose of sunitinib, even after dose reduction, was effective against GIST.

GISTs exhibit a varying degree of malignancy potential, and risk stratification is important when considering the treatment strategy. One of the most popular risk-stratification approaches is the modified-Fletcher classification (4). According to this system, our case, whose tumor was classified as high-risk because of a mitotic index of >10 per 50 HPFs, has a 15%-20% risk of recurrence and is recommended to receive adjuvant imatinib for 3 years (5). Furthermore, GISTs usually harbor activating mutations in either KIT (75%-80%) or PDGFRα (5%-10%) (6), and the genotype has been identified as a predictor of the response to imatinib. In the present case, a mutation at KIT in exon 11 was detected, implying a better response to imatinib (7).

For recurrent and unresectable GISTs, the first recommended TKI is imatinib. However, some patients show primary or early resistance to imatinib, and acquired resistance develops after a median of approximately two years of treatment. In case of resistance, sunitinib, an oral multitargeted receptor TKI, is the next choice. Sunitinib and imatinib are similar in that they both bind within the ATP-binding domain of KIT and PDGFRs, but the significant difference between the two is that sunitinib inhibits VEGFR kinases, which are important in tumor-related angiogenesis, whereas imatinib cannot inhibit them. This is thought to be the main reason underlying the clinical benefit of sunitinib for imatinib-resistant GISTs (3). Considering these mechanisms, imatinib-intolerable patients, such as the patient in the pre-

Sunitinib is recommended to be used at a dose of 50 mg/day for 4 weeks followed by a 2-week off period according to a phase I trial (8). However, Japanese post-marketing surveillance has reported that as many as 60% of patients with GIST require dose reduction (9), so modification of the drug dose and treatment schedule is usually needed. To our knowledge, the present case is the first to show the effectiveness and safety of escalating the sunitinib dose even after a previous dose reduction. In addition to escalation, modifying the treatment schedule might also be effective. Preclinical data have reported tumor growth during the off-dosing period, suggesting that sunitinib might be effective when used continuously (10). Furthermore, a phase II trial showed that the concentration of sunitinib decreased to predose levels during a 14-day rest period (11). Based on these reports, various modifications of sunitinib administration have been considered. For example, a phase I trial of sunitinib for two weeks followed by a one-week off period (2/1 schedule) has shown tolerability among patients. This 2/1 schedule kept the sunitinib concentration detectable even on day 1 of course 2, while no significant drug accumulation between courses was detected. This indicates that the 2/1 schedule can prolong sunitinib exposure without inducing intolerance (12).

Kinase genotype has also been shown to influence the clinical activity of sunitinib. In detail, the progression-free survival (PFS) is known to be shorter (5.1 to 7.0 months) for patients with primary \textit{KIT} exon 11 mutations than for those with \textit{KIT} exon 9 mutations or with a wild-type geno-
type (13, 14). It is difficult to compare the PFS of the present case with the values in other cases because our patient used sunitinib as the first-line treatment due to intolerance of imatinib. However, we can safely say that sunitinib was effective in our case.

Supplying sufficient medication is also believed to be important, as demonstrated in this case; whereby a proton pump inhibitor against gastritis, topical steroids against stomatitis and hand-foot syndrome, and an ACE inhibitor and calcium channel blocker against hypertension were administered.

In conclusion, the present findings suggest that escalation of sunitinib can be considered after reducing the dose due to adverse events and that the treatment schedule can be modified when required.

The authors state that they have no Conflict of Interest (COI).
