A 65-year-old man with an occupational history of asbestos exposure developed dysphagia and vomiting. Clinical examinations at onset revealed a dilated esophagus with smooth narrowing at the gastroesophageal junction and no apparent tumor in and around the esophagus. Achalasia was suspected. Dysphagia progressed gradually and examinations performed three months after the onset disclosed a tumor in the pleural and the peritoneal cavities. At laparotomy, the tumor extended from the pleural cavity into the peritoneal cavity. Histological examination of the biopsied specimen demonstrated malignant mesothelioma. We report the first case of malignant pleural mesothelioma presenting as achalasia.

(Internal Medicine 33: 624-627, 1994)

Key words: asbestos exposure, dysphagia, pleural effusion, dilated esophagus, hyaluronic acid

Introduction

Malignant mesothelioma is a relatively rare tumor of mesodermal origin which arises in the pleural, pericardial or peritoneal cavity. Asbestos exposure is responsible in the majority of this type of tumor. In patients with malignant pleural mesothelioma, the most common presenting symptoms are chest pain and dyspnea, and a pleural effusion frequently develops. In this report, we describe a case of malignant pleural mesothelioma in whom the initial symptoms and clinical findings were similar to those of achalasia.

Case Report

A 65-year-old man was admitted to the hospital in April 1992 because of dysphagia, vomiting and body weight loss. There was an occupational history of exposure to asbestos. The patient had been treated for hypertension and asbestosis at another hospital since 1958. He developed dysphagia and vomiting about one month before admission. As barium esophagram revealed dilatation of the esophagus, achalasia was suspected. He was referred to the hospital for further evaluation and treatment.

On admission the body temperature was 36.6°C and the pulse rate was 78/min. The blood pressure was 140/88 mmHg. Physical examination was negative except that he was thin and alert. Laboratory findings are listed in Table 1. Leukocytosis and an elevated erythrocyte sedimentation rate were found.

Malignant Mesothelioma with Achalasia

There were no malignant lesions in the esophagus and the stomach.

On manometric examination, the pressure of the lower esophageal sphincter was elevated to more than 60 mmHg. Swallowing decreased the pressure, while administration of anticholinergic drugs had little effect on the pressure. Manometric findings did not completely satisfy the criteria of achalasia. Dysphagia progressed gradually during hospitalization. An endoscope passed through the gastroesophageal junction without difficulty at the time of admission, whereas it could not be passed through at two months after admission. A CT scan of the chest and the upper abdomen (Fig. 5), performed after oral and intravenous administration of contrast material, demonstrated a mass which had not been recognized in the CT scan taken at the previous hospital about three months before and at our hospital on admission. The lower esophagus and the descending aorta were involved in the tumor.

Digital subtraction angiography (DSA) of the aorta (Fig. 6) disclosed a hypervascular tumor in the pleural cavity and a rightward deflection of the descending aorta. Sagittal magnetic resonance imaging (MRI) of the upper body revealed that the tumor extended from the pleural cavity into the peritoneal cavity. Cytologic examinations of the pleural effusion were negative. Hyaluronic acid in the pleural effusion was high at a concentration of more than 15 µg/ml (normal range: 2.5–5.5 µg/ml). We made a tentative diagnosis of malignant mesothelioma.

The patient underwent an operation because of inability to

take a meal. At laparotomy, the tumor invaded the diaphragm and extended to the peritoneal cavity including the back of the pancreas and the left lobe of the liver. The tumor involved the lower portion of the esophagus.

As complete resection of the tumor was impossible, some palliative procedures were carried out and biopsy specimens were taken for pathological examination. Hematoxylin and eosin (HE) stain of biopsied specimens (Fig. 7) revealed epithelial tumor cells proliferating into the glandular structure. On colloidal iron stain (Fig. 8), tumor cells stained blue but did not stain after treatment with hyaluronidase. Pathological diagnosis of malignant mesothelioma was made. He died six months after the onset of symptoms.

**Discussion**

Malignant mesothelioma is relatively rare, but it is an increasingly recognized tumor of mesodermal origin which arises from the pleura, the peritoneum or less frequently the pericardium. Wagner et al first reported the close association of asbestos exposure and malignant mesothelioma in 1960 (1). It

is now generally accepted that asbestos is the most important etiologic agent of malignant mesothelioma (2-5). The latent period between asbestos exposure and development of malignant mesothelioma usually exceeds 20 years and sometimes may be 60 years (3). The most common presenting symptoms of malignant pleural mesothelioma are chest pain and dyspnea (5). Chest radiography frequently reveals a pleural effusion (4, 5). In the present patient, there was an occupational history of asbestos exposure and the latent period was about 35 years. The patient developed dysphagia and vomiting as initial symptoms. Barium esophagram and endoscopy revealed the dilated esophagus with stenosis at the gastroesophageal junction. Although we made every effort to rule out mechanical stenosis due to malignancy, we could not recognize any tumor in and around the digestive tracts at that time. However, we had a strong suspicion of malignancy, especially malignant pleural mesothelioma from the onset. Therefore, our tentative diagnosis was secondary achalasia due to yet undefined malignancy. We established the diagnosis of malignant pleural mesothelioma three months after the onset of symptoms, when the tumor was apparently recognized in the pleural and the peritoneal cavities. Thus, we concluded in retrospect that dilatation of the esophagus on the onset in our patient resulted from secondary achalasia due to malignant pleural mesothelioma. Secondary achalasia has been reported to occur in patients with a variety of malignancies (6). The most common malignancy is gastric carcinoma of the distal esophagus (6-8). To our knowledge, secondary achalasia due to malignant mesothelioma has not been reported so far. The pathogenesis of secondary achalasia remains unclear. Direct invasion of the distal esophageal myenteric plexus or neuropathic effect of an underlying malignancy has been thought to be the cause of secondary achalasia (7, 8). As malignant mesothelioma usually develops diffusely along parietal and visceral surfaces, direct invasion of the myenteric ganglia of the esophagus seems unlikely in our patient.

As to the pathologic diagnosis, HE stain of biopsied specimen showed epithelial malignant cells forming glandular structure, which resembled histological features of adenocarcinoma. On colloidal iron stain, tumor cells were stained blue, while the cells did not stain after treatment with hyaluronidase. This result indicates the presence of hyaluronic acid in the tumor cells. Furthermore, PAS stain with diastase digestion was negative. These pathologic findings are consistent with the diagnosis of malignant mesothelioma (9, 10).

The prognosis of malignant mesothelioma is extremely poor. The majority of the patients have been reported to die within the first year of the onset of symptoms (4, 11, 12). The tumor in our patient grew rapidly and he died 6 months after the onset of symptoms. In conclusion, we describe here the first reported case of malignant pleural mesothelioma presenting as achalasia.
