Mucosa-associated lymphoid tissue (MALT) lymphoma is often mis-diagnosed as a benign tumor. Dissemination to other sites occurs in MALT lymphoma. We report a 60-year-old man with gastric and pulmonary tumors of MALT lymphoma which occurred 5 years apart. Initially, the gastric tumor had been diagnosed as reactive lymphoreticular hyperplasia. To determine whether the two tumors arose from the same malignant clone, we amplified and sequenced the complementarity-determining region 3 of the immunoglobulin heavy chain gene using the polymerase chain reaction (PCR). The sequences were identical except for 11-nucleotide difference, suggesting identical clonality.

(Internal Medicine 34: 220-223, 1995)

Key words: reactive lymphoid hyperplasia, polymerase chain reaction, complementarity-determining region 3

Introduction

Mucosa-associated lymphoid tissue (MALT) lymphoma is one of the low-grade B-cell lymphomas (1). It occurs in the gastro-intestinal tract, lung, salivary gland, and thyroid, and usually remains at the primary site (2). The disease is characterized by indolent progression leading to a prolonged clinical course (2). The tendency to remain at the primary site and specific dissemination to other mucosal sites are characteristic features of MALT lymphoma that are poorly understood. The diagnosis of MALT lymphoma is difficult to make sometimes, and MALT is frequently mis-diagnosed as reactive lymphoreticular hyperplasia (RLH) or some other benign tumor, as the abnormal centrocyte-like cells surrounding the normal reactive B-cell follicles are few.

Recent progress in molecular biological analysis has made it possible to detect small monoclonal B-cell populations in paraffin-embedded tissues using the polymerase chain reaction (PCR). In B-cell malignancies, amplification by PCR of the complementarity-determining region 3 (CDR3) that is generated by V-D-J joining of the immunoglobulin heavy chain gene is useful (3, 4) for the demonstration of monoclonality of the disease. By sequencing the CDR3 of separate tumors, it is possible to determine whether the malignant cells are derived from the same origin, since the pattern of V-D-J joining is very variable and is specific for each B-cell clone.

Here we report a patient who had MALT lymphoma in the stomach which was diagnosed initially as RLH and who developed the same type of MALT lymphoma 5 years later. We amplified and sequenced the respective CDR3 regions of the two specimens to confirm clonality.

Case Report

A 60-year-old man was admitted to an affiliated hospital complaining of epigastric discomfort. A large submucosal tumor was found in the stomach, and a gastrectomy was performed. The pathologic diagnosis of the excised tumor was RLH. The patient was followed without any further therapy.

Five years later he was readmitted to our hospital because of an abnormality seen on a chest roentgenogram ordered as part of a routine examination. Chest radiographs revealed alveolar shadows in the right lower lung field. As no pathogenic bacteria were detected on sputum culture, and treatment with antibiotics...
did not show any improvement, a transbronchial lung biopsy (TBLB) was performed to evaluate the cause of the alveolar process. The pathologic diagnosis of the TBLB samples was MALT lymphoma. A lobectomy was performed.

**Materials and Methods**

**Pathologic analysis**

We reviewed formalin-fixed, paraffin-embedded sections of the gastric tumor and specimens of the excised lobe of the lung which were stained with hematoxylin and eosin (HE). The samples were obtained with informed consent.

**PCR analysis**

DNAs were extracted from paraffin-embedded samples of the gastric tumor using a method previously reported (5) and from the resected pulmonary lobe using the standard proteinase-phenol-chloroform method (6). Approximately 0.1 μg of DNA was subjected to PCR (3). Semi-nested PCR was performed to amplify the CDR3 sequences, in which primers were directed to the joining region (first-round primer, LJH: 5′-TGAGGAGACGGTGACC-3′; nested second-round primer, VLJH: 5′-GTGACCAGGGTNCCTTGGCCCCAG-3′) and to the conserved framework-three segment of the variable region [5′-ACACGGC(C/T)(G/C)TGTATTACTGT-3′] (7, 8). The PCR consisted of 3 minutes pre-heating at 94°C, 40 cycles of 1 minute denaturing at 94°C, 1 minute annealing at 55°C and 1 minute extension at 74°C, and a 10 minutes post-extension at 74°C. The PCR was performed on a PC-700 thermocycler (Astec, Tokyo, Japan). Products were electrophoresed using a 12% polyacrylamide gel, and the gel was stained with ethidium bromide.

**Cloning and sequencing of PCR products**

PCR products were ligated into pUC18 plasmid vectors using a Sure Clone PCR ligation kit (Pharmacia LKB, Tokyo, Japan). Nucleotide sequences were determined by fluorescence on an Autosequencer 373A (Applied BioSystem, Foster City, CA, USA) using vector-specific primers.

**Results**

The specimen of the gastric tumor which had been diagnosed initially as RLH showed centrocyte-like cells infiltrating around reactive B-cell follicles with destruction of the epithelial layers. These findings are compatible with the histologic features of a low-grade B-cell lymphoma of the MALT type (1) (Fig. 1A). Histologic examination of the resected lung also revealed MALT lymphoma with infiltration of medium-sized cells (Fig. 1B).

A single band representing rearrangement of the immunoglobulin heavy chain gene was detected in both PCR prod-
Kawamata et al

Fig. 2. Electrophoresis of PCR products on a 12% polyacrylamide gel. Twenty μl of the PCR products were applied to each lane. Lane 1 is the PCR product of the stomach tumor and lane 2 is that of the pulmonary tumor. Single bands are detected in both lanes. The left lane is the PHY size markers (Takara, Kyoto, Japan).

Fig. 3. Nucleotide sequence of CDR3 of the samples. The upper sequence (Lung) is derived from the excised lung. The lower sequence (Stomach) is derived from the stomach tumor. The primer sequences (FR3A and VLJH) are shown with bold underlines. The variable region sequence (VH6), diversity region (D), and joining region (J6) are indicated by thin underlines. N segments (N) have no underline. Nucleotide differences between the two sequences are indicated by lower-case letters.

The immunoglobulin variable region of the two tumors in this study showed differences between the stomach and lung samples in nucleotides at 11 positions. Since Taq DNA polymerase lacks a proof-reading function, some point mutations occur during the PCR procedure (5). The frequency of a substitution of a nucleotide during a single cycle extension of PCR is estimated at 1/8000 (5). As we carried out 40 cycles of extension, the mutation rate in our amplification was estimated at 1/200. The number of point mutations found in our study was far more than that expected from the PCR procedure. Therefore, it is reasonable to assume that these mutations occurred during the development of the disease.

MALT lymphoma has been reported to be indolent, and to have a tendency to remain at the primary site. In the present case, the patient developed a tumor in the lung, not in the primary site of the gastrointestinal tract. This indicates that dissemination to other sites occurs in MALT lymphoma. Blazquez et al (15) have reported that mucosal dissemination to other sites occurs more frequently than has been previously reported.

It is conceivable that there are many patients with MALT lymphoma who are mis-diagnosed initially with other benign tumors. In such cases, an initial correct diagnosis and appropriate treatment will improve the lymphoma patient’s prognosis. When a patient is diagnosed as having reactive B-cell hyperplasia, it is important to rule out the presence of monoclonality in the tumor by PCR.

Discussion

In this study we showed by PCR that a gastric MALT lymphoma which had initially been diagnosed as RLH, and a pulmonary MALT lymphoma which had developed 5 years later in the same patient arose from the same clone.

In MALT lymphoma, normal reactive B-cell follicles exist, and only a few abnormal centrocyte-like cells are seen surrounding the follicles. This pathohistologic feature makes it difficult to diagnose the disease correctly, and MALT lymphoma has been misdiagnosed frequently as other benign tumors (13). In reactive B-cell hyperplasia, infiltrating lymphocytes do not have monoclonality, so that PCR analysis shows a smear pattern (9, 14), while a single band is detected in MALT lymphoma. Therefore PCR analysis is a very useful method to distinguish MALT lymphoma from other benign tumors, including RLH.

In MALT lymphoma, normal reactive B-cell follicles exist, and only a few abnormal centrocyte-like cells are seen surrounding the follicles. This pathohistologic feature makes it difficult to diagnose the disease correctly, and MALT lymphoma has been misdiagnosed frequently as other benign tumors (13). In reactive B-cell hyperplasia, infiltrating lymphocytes do not have monoclonality, so that PCR analysis shows a smear pattern (9, 14), while a single band is detected in MALT lymphoma.
