We describe a 60-year-old woman with leg pain. Although metastatic bone tumor and atypical cells mimicking signet-ring cells in the bone marrow picture were observed, systemic survey revealed no primary lesion. The patient died two months after admission from systemic progress of the disease. Autopsy revealed a small focus of adenocarcinoma within the right upper lobe of the lung and systemic metastases without any particular changes in the gastrointestinal tract. The tumor cells of the lung were diffusely positive for cytokeratin 7, whereas cytokeratin 20 immunoreactivity was weak and focal, and that supported the lung origin of the present tumor. Moreover, the tumor cells in the bone marrow showed a similar pattern in immunoreactivity. These findings suggest that cytokeratin 7 and cytokeratin 20 immunoreactivity is helpful for the premorten diagnosis of the metastatic tumor of unknown origin.

Key words: signet-ring cell carcinoma, immunohistochemistry, metastatic bone tumor

Introduction

Bone metastases are often the first manifestation of malignant diseases. Lung adenocarcinoma and uterine adenocarcinoma are reported to be the major primary site (1). However, in some cases the primary site of the bone metastases cannot be identified by systemic examination.

In the present paper, we describe a female patient with signet-ring cell-like adenocarcinoma of uncertain origin, which was found in the bone marrow picture. The autopsy findings and immunohistochemical analysis are also described.

Case Report

A 60-year-old woman was seen by a local physician with pain in her right lower extremity in February 1997. The patient had no evidence of occupational contaminants. For further examination, she was then referred to Tokushima University Hospital. On admission, she complained of pain in the right lower extremity without systemic pain. No cervical, axillar or inguinal lymph nodes were palpable, and physical examination revealed no remarkable findings. Laboratory examination was as follows: hemoglobin 10.9 g/dl, white blood cell count 5,100/µl with 50% neutrophils, 4% monocytes, 43% lymphocytes, platelet 15.3 x 10^4/µl, aspartate aminotransferase 18 U/l, alanine aminotransferase 15 IU/l, lactate dehydrogenase 381 U/l, alkaline phosphatase 4,560 IU/l, γ-glutamyl transpeptidase 23 U/l, amylase 48 U/l, total protein 6.7 g/dl, albumin 3.7 g/dl, creatinine 0.6 mg/dl, Na 142 mEq/l, K 3.9 mEq/l, Ca 8.3 mg/dl, erythrocyte sedimentation rate 26 mm/h, C-reactive protein 1.75 mg/dl. Serum tumor marker levels (normal range in parentheses) were as follows: squamous cell carcinoma-related antigen 0.79 ng/ml (< 1.5), carcinoembryonic antigen 2.0 ng/ml (<5.0), carbohydrate antigen 19-9 29 U/ml (<47), carbohydrate antigen 125 14 U/ml (<42) and neuron-specific enolase 5.9 ng/ml (<10).

Osteolytic change was observed in the right fibula and bone scintgram revealed multiple abnormal accumulations (Fig. 1). The patient was diagnosed as having metastatic bone tumor, and we performed systemic survey for the detection of the primary site. A small nodule in upper lobe of the right lung was observed in the chest computed tomography (CT) scan (Fig. 2). Examination with fiberoptic bronchoscope revealed no endoscopic findings and no malignant cells were obtained. Gastrointestinal examination, including endoscopy, and upper and lower barium series revealed no abnormal findings. No abnormal findings were observed in brain magnetic resonance imaging, cervical ultrasonogram, breast examination by a sur-
geon, abdominal CT or gynecological examination. Bone mar-
row picture demonstrated the presence of a small amount of
atypical cells mimicking signet-ring cells (Fig. 3).
Although the primary site was unknown, the patient was
diagnosed as having adenocarcinoma with bone marrow inva-
sion. Then she was treated with oral medication of 600 mg/day
of tegafur with uracil (UFT), but it was discontinued due to
gastrointestinal side effects. Palliative therapy with medication
of morphine hydrochloride and non-steroidal anti-inflamma-
tory drugs was effective for relief of the pain, but the disease
progressed and the patient died from complicated disseminated
intravascular coagulation on April 26, 1997.

Postmortem examination was performed. A small, ill-de-
defined nodule, 1.2×0.9 cm in diameter, was identified in the
upper lobe of the right lung. Microscopic examination revealed
that the lesion was well-differentiated adenocarcinoma com-
posed of mucin-containing tumor cells, which were identical to
those found in the bone marrow picture (Fig. 4). Immunohisto-
chemically, most tumor cells were strongly positive for
cytokeratin 7 (Dako) (Fig. 5), while cytokeratin 20 (Dako)
immunoreactivity was focal and weak. Numerous tumor emboli in the small vessels of the bilateral lungs, and systemic metastases to bone marrow, liver, spleen and kidney were observed. The tumor cells in the bone marrow also showed strong reactivity for cytokeratin 7 (Dako) (Fig. 6), while cytokeratin 20 (Dako) immunoreactivity was weak. No particular changes were seen in the stomach, pancreas, rectum, urinary bladder, or small and large intestine.

**Discussion**

Bone metastases are often the first manifestation of malignant diseases. Baron et al (1) examined 29 cases whose first sign of a tumor was a bone metastasis, and reported that lung adenocarcinoma and uterine adenocarcinoma were the major primary site. But, in some cases, the primary site of the bone metastases cannot be identified by systemic examination. Nakano et al (2) also examined 20 patients whose initial manifestation was bone metastasis, and reported that the primary site had not been detected within two months after presentation in three cases among these 20 patients. Lung cancer had been recognized by follow-up study in two of three cases, and autopsy revealed adrenal cancer in one case.

In the present case, a small nodule in upper lobe of the right lung was observed in chest CT scan and we performed examination with fiberoptic bronchoscope, but we obtained no endoscopic findings and no malignant cells in the specimen. On the other hand, we observed aggregation of signet ring-like atypical cells in the bone marrow picture. Signet-ring cell carcinomas have been found in a variety of organs, such as stomach, colon and breast, but primary lung adenocarcinoma with signet-ring cells is rare (3). Therefore, undetectable minute tumor in the gastrointestinal tract, as well as a small nodule in upper lobe of the right lung, was suspected as the primary site by premortem examination.

Postmortem examination revealed a small adenocarcinoma in the lung. To evaluate whether the lung tumor is metastatic or primary, we performed immunohistochemical analysis. The cytokeratins are a family of 40 kD to 70 kD intermediate filament proteins that are widely distributed in epithelial cells (4), and they are cataloged under the numbers 1 through 20 by Moll et al (5). Among the cytokeratins, cytokeratin 7 is expressed in specific subtypes of adenocarcinoma from ovary, breast and lung, whereas carcinomas from the gastrointestinal tract are found to remain negative (6–8). On the other hand, cytokeratin 20 is expressed on various adenocarcinoma, including colorectal carcinoma, adenocarcinomas of the gallbladder and bile ducts, and ductal cell adenocarcinoma of the pancreas, but is not expressed on lung carcinoma (9). Moreover, Loy and Calaluce (10) examined 151 cases with adenocarcinoma and reported that the immunophenotype of cytokeratin 7 positive/cytokeratin 20 negative was seen in 86% of pulmonary adenocarcinomas and 0% of colonic adenocarcinomas. Therefore, the cytokeratin 7 predominant pattern of the present case supported the diagnosis of pulmonary adenocarcinoma. We could not perform immunohistochemical analysis of the bone marrow specimen on premortem examination, but the postmortem examination revealed that tumor cells in the bone marrow also showed the immunophenotype of cytokeratin 7 positive/cytokeratin 20 negative (Fig. 6). Therefore, premortem immunohistochemical examination of the tumor cells in the bone marrow might have been helpful for the diagnosis of the primary site in the present case.

In the present paper, we describe a female patient with signet-ring cell like adenocarcinoma of uncertain origin, who was diagnosed as pulmonary adenocarcinoma by postmortem examination. These findings suggest that immunohistochemical examinations of adenocarcinomas of uncertain origin with cytokeratin antibodies could be helpful for the premortem diagnosis of the primary site.
Cytokeratin 7-positive Lung Adenocarcinoma
