MCP-1 and MIP-1A Gene Polymorphisms in Japanese Patients with Sarcoidosis
Toshinori Takada, Eiichi Suzuki, Kazuaki Morohashi, Kentaro Omori and Fumitake Gejyo

Abstract

Objectives  Monocyte chemoattractant protein (MCP)-1 and macrophage inflammatory protein (MIP)-1α exhibit chemotactic activity toward macrophages/monocytes and induce the production of inflammatory cytokines affecting granuloma formation. Recently, a single nucleotide polymorphism (SNP) in the MCP-1 distal regulatory region and a dinucleotide repeat in the MIP-1A gene promoter region were identified. We investigated the relationships between the polymorphisms and susceptibility to sarcoidosis, clinical manifestations, and BALF findings of sarcoidosis.

Methods  The polymorphisms of the MCP-1 and MIP-1A genes in 118 patients with sarcoidosis and 145 healthy control subjects were examined. The MCP-1 polymorphism was genotyped by a PCR-restriction fragment length polymorphism method and the MIP-1A genotype was determined using PCR.

Results  No significant difference in the genotype distribution or in the allele frequency between the patients and control subjects was observed. We found no relationship between the polymorphisms and the serum ACE level, organ involvement, roentgenographic stages, or deterioration in chest radiographs during the follow-up. A significant difference in the absolute counts of AMs in BALF of 51 patients among the genotypes of the MCP-1 gene was found (p=0.048). The AM counts in BALF of the G/A and G/G genotypes were significantly increased compared with that of the A/A genotype (p<0.05).

Conclusion  The polymorphisms of the MCP-1 and MIP-1A genes do not play a substantial role in genetic predisposition for sarcoidosis or in clinical manifestations of sarcoidosis in this Japanese population. The MCP-1 SNP might be related to the recruitment of monocytes/macrophages to the alveolar spaces in sarcoidosis.

Key words: genetic susceptibility, microsatellite, PCR-RFLP, single nucleotide polymorphism

Introduction

Sarcoidosis is a systemic granulomatous disorder of unknown etiology involving multiple organs (1, 2). Sarcoid granuloma typically shows a center of epithelioid cells surrounded by CD4+ lymphocytes, some CD8+ lymphocytes, giant cells, and mature macrophages. In the affected organs, activated T cells and macrophages release a number of cytokines that provide the stimulus for progress toward the granuloma formation and, in some cases, to fibrosis. The recruitment of macrophages and T cells into the affected organ is thought to be an important step in the development of sarcoidosis.

Monocyte chemoattractant protein (MCP)-1 and macrophage inflammatory protein (MIP)-1α are members of the C-C chemokine supergene family (3, 4). MCP-1 is a monocyte-specific chemotactic factor produced by a wide variety of cell types, including monocytes, fibroblasts, vascular endothelial cells, and smooth muscle cells. MIP-1α is produced by appropriately stimulated T cells, alveolar and peritoneal macrophages, neutrophils, monocytes, airway epithelial cells, and fibroblasts, and has been shown to activate mast cells and basophils to be chemoattractic for T cells and monocytes. Both chemokines contribute to acute and cellular immune tissue responses via recruitment and activation of macrophages and T cells inducing the production of inflammatory cytokines which affect granuloma formation (5–8). In sarcoidosis, the elevation of the MCP-1 and MIP-1α levels in bronchoalveolar lavage fluid (BALF) and the up-regulated expression of these chemokines in macrophages in the affected organ have been shown (9, 10).

The human MCP-1 gene transcript appears to be under the control of two distinct areas of the 5'-flanking region of the gene. Recently, two single nucleotide polymorphisms (SNPs) in the MCP-1 distal regulatory region were identified and the SNP at position –2,518 was found to affect the transcriptional activity of the regulatory region, and monocyte MCP-1 production (11). As for the MIP-1A gene, a biallelic dinucleotide microsatellite repeat was recently identified (12). The repeat occurs within the promoter region, making it an ideal marker for association and linkage studies in inflammatory diseases.

In the present study, we investigated the MCP-1 and MIP-
1A polymorphisms to clarify whether these polymorphisms are associated with susceptibility to sarcoidosis, clinical manifestations, and BALF findings of sarcoidosis in a Japanese population.

**Methods**

**Study Population**

One hundred eighteen Japanese subjects with sarcoidosis were recruited from the clinic at the Niigata University Hospital. Sarcoidosis was diagnosed on the basis of the typical clinical features and the presence of epithelioid cell granulomas in biopsy specimens from the lung, skin, or lymph nodes. Forty-four of the cases were men and 74 were women. The average age of the patients at diagnosis was 45.1 years with a range between 19 and 74 years. Regarding the roentgenographic stage of the patients at the first visit to our hospital, all but 10 had chest X-ray evidence of sarcoidosis, 59 with stage I, 41 with stage II, and eight with stage III disease.

As healthy controls, 145 unrelated healthy Japanese subjects were selected. They consisted of 84 men and 61 women with a mean age of 40.9 years and a range between 21 and 70 years. They did not have any abnormalities based on physical examination, chest radiography, electrocardiogram (ECG), urinalysis, and routine laboratory blood testing. None were receiving medication at the time of the evaluation. All of the subjects in the study gave written informed consent for enrollment in the study and this study was approved by the Committee of Ethics, Niigata University.

**Determination of the MCP-1 and MIP-1A genotypes**

DNA was extracted from peripheral leukocytes with standard techniques. The polymerase chain reaction (PCR)-restriction fragment length polymorphism method was performed as described by Rovin et al (11) for MCP-1 genotyping. Specific oligonucleotide primers (5'-CCG AGA TGT TCC CAG CAC AG-3', and 5'-CTG CTT TGC TTG TGC CTC TT-3') were utilized with PCR to amplify a 930 bp segment of the MCP-1

**Figure 1. Determination of MCP-1 and MIP-1A genotypes.** The left lane of each panel contains markers. Panel A shows part of a representative 1% agarose gel stained with ethidium bromide and photographed under ultraviolet transillumination after PCR and digestion by Pvu II for MCP-1 genotyping. The upper band of 930 bp is the G allele and the lower band of 708 bp is the G allele (arrowheads). The A/A type is shown as a single upper band, the G/G type as a single lower band, and the G/A type as a double band. Panel B shows part of a representative 12% polyacrylamide gel stained with ethidium bromide and photographed under ultraviolet transillumination after PCR for MIP-1A genotyping. The upper band is the (TA)₆ allele and the lower band is the (TA)₄ allele (arrowheads). The (TA)₆/(TA)₆ type is shown as a single upper band, the (TA)₄/(TA)₄ type as a single lower band, and the (TA)₆/(TA)₄ type as a double band.
5'-flanking region between nucleotide −1,817 and −2,746 relative to the major transcriptional start site defined by Ueda et al (13). PCR was performed using denaturation at 94°C for 3 minutes, followed by 35 cycles at 94°C for 30 seconds, 60°C for 30 seconds, and 72°C for 30 seconds, and a final extension at 72°C for 3 minutes (DNA Thermal Cycler 9600; Perkin Elmer-Cetus, Norwalk, CT). The PCR products were digested with 2.0 U of Pvu II (Takara-Shuzo, Kyoto) at 37°C for 2 hours, and run on a 1% ethidium bromide-agarose gel. Pvu II digested the 930 bp DNA segment from G/G homozygous individuals into 708 and 222 bp fragments. DNA from A/A homozygous individuals was not cut with Pvu II. DNA from G/A heterozygous individuals showed the expected fragments at 930, 708, and 222 bp (Fig. 1A).

The PCR for MIP-1A genotyping was performed using the following primers: 5'-TGT ATT TTT TTC CAT GCT TAG GGT TG-3', and 5'-TCA GTG GTT AAA AAA AGC AAG ATA CGA-3'. PCR cycles were as follows: 94°C for 3 minutes followed by 35 cycles each of 94°C for 30 seconds, 53°C for 30 seconds, and 72°C for 30 seconds. A final extension step was carried out at 72°C for 3 minutes. The PCR products were visualized on a 12% polyacrylamide gel (acrylamide: bisacrylamide 19: 1) containing 10% glycerol stained with ethidium bromide (Fig. 1B). Samples that exhibited a single band were sequenced using the BigDye terminator cycle sequencing kit (PE; Applied Biosystems, Foster City, CA). Sequencing revealed a biallelic dinucleotide microsatellite repeat starting at position (−906) relative to the transcription site as described by Al-Sharif et al (12).

**Bronchoalveolar lavage**

Bronchoscopy with BAL was performed on 51 patients with sarcoidosis with the informed consent of the patient as part of the routine clinical management of sarcoidosis as previously described (14). Briefly, four 50-ml aliquots of 0.9% NaCl were instilled into the middle lobe. Each aliquot of infused fluid was immediately aspirated gently. The recovered BALF was strained into 708 and 222 bp fragments. DNA from A/A homozygous individuals was not cut with Pvu II. DNA from G/A heterozygous individuals showed the expected fragments at 930, 708, and 222 bp (Fig. 1A).

The allele frequencies and genotypes for the MCP-1 and MIP-1A polymorphisms are summarized in Table 1. As for MCP-1 genotypes, of the 118 sarcoidosis patients, 15 had the A/A genotype (12.7%), 57 the G/A type (48.3%), and 46 G/G type (39.0%). The frequency of A allele was 36.9%. Of the 145 healthy control subjects, 9 were type A/A (6.2%), 66 were G/A (45.5%), and 70 were G/G (48.3%). The frequency of A allele was 29.0%. No significant difference in the genotype distribution or in the allele frequency between the sarcoidosis patients and healthy control subjects was observed. As for MIP-1A genotype of the 116 sarcoidosis patients, 15 had the (TA)4/(TA)4 genotype (12.7%), 57 the (TA)4/(TA)6 type (42.7%), and 46 (TA)6/(TA)6 type (49.0%). The frequency of (TA)6 allele was 29.7%. No significant difference in the genotype distribution or in the allele frequency between the sarcoidosis patients and healthy control subjects was observed.

We then examined the relationship with the serum ACE level, organ involvement, roentgenographic stages, and deterioration in chest radiographs during the follow-up (Table 2). Cases of eye (n=85), skin (n=12), heart (n=12) and involvement of three or more organs (n=25) were examined. We found no significant correlation with the MCP-1 or MIP-1A genotype.

Next, we reviewed the BAL findings in 51 of the 118 patients who underwent bronchoscopy with BAL as part of the routine clinical management of sarcoidosis. The other 67 pa-

### Results

The allele frequencies and genotypes for the MCP-1 and MIP-1A polymorphisms are summarized in Table 1. As for MCP-1 genotypes, of the 118 sarcoidosis patients, 15 had the A/A genotype (12.7%), 57 the G/A type (48.3%), and 46 G/G type (39.0%). The frequency of A allele was 36.9%. Of the 145 healthy control subjects, 9 were type A/A (6.2%), 66 were G/A (45.5%), and 70 were G/G (48.3%). The frequency of A allele was 29.0%. No significant difference in the genotype distribution or in the allele frequency between the sarcoidosis patients and healthy control subjects was observed.

As for MIP-1A genotype of the 116 sarcoidosis patients, 15 had the (TA)4/(TA)4 genotype (12.7%), 57 the (TA)4/(TA)6 type (34.5%), and 46 (TA)6/(TA)6 type (52.6%). The frequency of (TA)6 allele was 30.2%. Of the 145 healthy control subjects, 12 were type (TA)4/(TA)4 (8.3%), 62 were (TA)4/(TA)6 (42.7%), and 71 were (TA)6/(TA)6 (49.0%). The frequency of (TA)6 allele was 29.7%. No significant difference in the genotype distribution or in the allele frequency between the sarcoidosis patients and healthy control subjects was observed.

The allele ratios and genotype distributions in sarcoidosis patients and control subjects, roentgenographic stages, and organ involvement among the three genotypes were analyzed with the chi-square test. The Fisher's exact test was also applied for comparison of small populations with expected values of less than five. The comparison of the serum level of ACE, and the percentage and the absolute count of alveolar macrophages (AMs) and lymphocytes in BALF among the genotypes was tested with the Kruskal-Wallis rank test. The Mann-Whitney U-test was applied for comparison of the serum ACE level and the percentage and absolute count of BALF cells between the genotypes. A p value $<$0.05 was considered significant.

patients did not undergo BAL or yield a sufficient amount of BALF to be evaluated. Nine of the 51 patients had A/A type (17.7%), 25 G/A type (49.0%), and 17 G/G type (33.3%) for MCP-1 genotypes. The genetic distribution was not different from that of all the 118 patients. We tested the correlations between the genotypes and the percentage and the absolute count of AMs in BALF. Although no significant difference in the percentages of AMs was observed among the genotypes, a significant difference in the absolute count of AMs was found (p=0.048) (Fig. 2). Comparing AM counts between the genotypes, the AM counts of the G/A and G/G genotypes were significantly higher than that of the A/A genotype (p=0.044 and p=0.012, respectively) (Fig. 2B). No significant difference in the absolute count of AMs was observed between the G/A and G/G genotypes (p=0.691). There was no significant relationship with the percentage or the absolute count of AMs or lymphocytes for the MIP-1 genotypes (data not shown).

MCP-1, MIP1A Polymorphisms in Sarcoidosis

Discussion

The present study showed a SNP at position −2,518 of the MCP-1 gene 5′ flanking region and a biallelic dinucleotide microsatellite repeat polymorphism within the promoter region of the MIP-1A gene in Japanese patients with sarcoidosis. Although we found no significant difference in the genotype or allele frequency between the patients and control subjects and no relationship between the polymorphisms and the serum ACE level, organ involvement, roentgenographic stages, or deterioration in chest radiographs during the follow-up, a significant difference in the absolute counts of AMs in BALF among the genotypes for the MCP-1 gene was found. Our findings indicate that the polymorphisms do not play a substantial role in the genetic predisposition for sarcoidosis or in clinical manifestations of sarcoidosis in this Japanese population and that the MCP-1 promoter SNP might be related to the recruitment of monocytes/macrophages to alveolar spaces in sarcoidosis.

The current consensus regarding its pathogenesis is that sarcoidosis results from exposure of genetically susceptible hosts to particular environmental factors (15). Some polymorphisms have been reported to be involved in the susceptibility to sarcoidosis, in disease severity and progression, or in disease prognosis (14, 16–18). Up-regulated expression of MCP-1 in the affected organ of sarcoidosis has been shown (9, 19). MCP-1 exhibits chemotactic activity toward monocytes/macrophages and induces the production of inflammatory cytokines affecting granuloma formation. Although the SNP of MCP-1 was not associated with susceptibility to the disease, the absolute counts of AMs in BALF of the G/A and G/G genotypes were significantly increased compared with that of the A/A genotype in this sarcoidosis population. Rovin et al showed that a G allele at −2,518 affected the transcriptional activity of the distal regulatory region, and increased monocyte MCP-1 production (11). This SNP does not alter the known transcription factor binding sites of the MCP-1 distal regulatory region, but may affect a previously unidentified site. The G allele at −2,518 might possibly enhance the binding specificity of this motif to an unknown transcription factor resulting in an increase of the MCP-1 expression. Individuals who carry the variant A allele might have decreased recruitment of monocytes, because of low MCP-1 production. Another possible explanation for the association between the SNP and the increased AM count in BALF could be a linkage disequilibrium between this SNP and another as yet unknown functional mutation elsewhere in the MCP-1 sequence. The mechanistic details remain unclear, but our results suggest that the MCP-1 gene SNP at −2,518 might play an important role in the recruitment of monocytes/macrophages to the alveolar spaces in sarcoidosis. The recruitment of macrophages and T cells into the affected organ is thought to be an important step in the development of sarcoidosis. Further studies will be needed to elucidate whether the SNP is associated with the detailed radiographic findings or pulmonary function tests. The serum and BALF MCP-1 levels were significantly elevated in sarcoidosis patients compared with healthy controls (9, 20). Studies to investigate the relationship between the MCP-1 genotypes and MCP-1 levels in serum and BALF are currently underway.

We studied 145 healthy Japanese individuals and found the G allele/A allele ratio was 0.71/0.29 in this population in contrast to 0.29/0.71 in a Caucasian population in a previous report (11). The SNP in the MCP-1 promoter region was associated with the presence of cutaneous vasculitis among patients with SLE (21) and the presence and severity of asthma and increased eosinophil levels (22). However, the racial heterogeneity of the SNP in the diseases has not been examined. It has been reported that MCP-1 plays an important role in the production and development of various inflammatory diseases (23–25). Further investigation of the general association of the SNP with other inflammatory diseases in Caucasians and in Asian groups is needed.

In sarcoidosis, the MIP-1α level in BALF was elevated and a substantial expression of cell-associated MIP-1α was detected in the macrophages including both AMs and interstitial macrophages, and interstitial pulmonary fibroblasts by immunohistochemical analysis (10). Al-Sharif et al identified a biallelic dinucleotide repeat within the promoter region of the MIP-1A gene (12). The functional significance of dinucleotide repeat regions is being increasingly realized with respect to their influence on the DNA structure, gene expression, and genomic (in)stability (26, 27). The present findings showed no significant difference in the MIP-1A genotype between sarcoidosis patients and healthy controls and no association between the genotype and organ involvement. The MIP-1α expression from mononuclear cells is stimulated in vitro by lipopolysaccharide and IL-1 (28). The increased production of IL-1, TNF-α or PDGF by AMs from patients may function in an autocrine or paracrine fashion to up-regulate the expression of MIP-1α. Recently, novel SNPs at four sites within the MIP-1A gene and a relationship between one of the SNPs and atopic dermatitis were found in a Japanese population (29). MIP-1α is involved in inflammation, wound healing and hematopoiesis (8, 30–32). Study of the association of the SNPs with sarcoidosis and other diseases is necessary.
