Abstract

The applicability of monitoring concentrations of serum KL-6 and serum surfactant protein-D (SP-D) in the detection of methotrexate-associated lung injury (MTX pneumonitis) in patients with rheumatoid arthritis (RA) was investigated. The concentrations of these markers, sequentially measured in two patients with RA complicated with MTX pneumonitis, were increased in accordance with the severity of MTX pneumonitis. Conversely, the concentrations of these markers were decreased with the improvement of MTX pneumonitis, suggesting that the monitoring of these markers could be applicable not only for detecting the onset of MTX pneumonitis, but also for detecting the therapeutic response of MTX pneumonitis.

Key words: MTX, pneumonitis, pulmonary tuberculosis, pulmonary adenocarcinoma, type II pneumocyte

Introduction

A weekly pulse of low-dose methotrexate (MTX) is an effective and the most popular therapy for rheumatoid arthritis (RA). One of the most serious complications of MTX therapy is MTX-associated lung injury (MTX pneumonitis) (1). Golden et al suggested that preexisting interstitial pneumonia (IP) characterized by radiographic interstitial infiltrates may predispose patients with RA to developing MTX pneumonitis (2). Moreover, Alarcon et al listed the risk factors for MTX pneumonitis such as old age (≥60 years old), diabetes mellitus, previous use of disease-modifying antirheumatic drugs, and hypoalbuminemia (<3.9 g/dl) in addition to preexisting IP in a multicenter, case-control study (3). Previous reports and our experience indicate that MTX pneumonitis is emerging as one of the most unpredictable complications; it is not dose-dependent, and it is a type of hypersensitivity pneumonitis (4).

MTX has tremendous therapeutic value in RA patients even with preexisting IP; therefore, preexisting IP should be a relative, not an absolute contraindication in prescribing MTX to RA patients. Because 40% of RA patients have some pulmonary dysfunction (5, 6), the problem of distinguishing MTX pneumonitis from preexisting IP exists. In this regard, a marker that can not only detect the onset of MTX pneumonitis but can also differentiate MTX pneumonitis from preexisting IP is highly desired.

KL-6 and SP-D are recently developed serum markers useful for detecting hypersensitivity pneumonitis, idiopathic IP and IP associated with collagen vascular diseases (7-10). However, the usefulness of these serum markers for detecting MTX pneumonitis has not yet been established. We hypothesized that KL-6 and SP-D can be valuable for use as markers in detecting the onset of MTX pneumonitis as well as for differentiating MTX pneumonitis from preexisting IP. In this study, we demonstrated that these serum markers show promise in detecting the onset of MTX pneumonitis, in differentiating MTX pneumonitis from preexisting IP, and in monitoring the therapeutic outcome of MTX pneumonitis.

Materials and Methods

Measurement of serum KL-6 concentration

The concentration of serum KL-6 antigen was measured using a sandwich-type enzyme-linked immunosorbent assay (ELISA) (11) kit (Eitest KL-6, Eisai Co., Tokyo, Sanko Pharmaceutical Co., Tokyo).

Measurement of serum SP-D concentrations

The concentration of serum SP-D antigen was measured using a sandwich-type ELISA (12) kit (SP-D kit, Yamasa Co.,...
Miyata et al

Patients

Patient 1

A 66-year-old man suffering from RA since 1995 was undergoing treatment with gold salt injection and prednisolone, followed by a 2.5 mg/day to 5 mg/day weekly pulse of MTX initiated in March 1997, as shown in Fig. 1. The representative laboratory data when the weekly pulse of MTX was initiated were as follows; erythrocyte sedimentation rate, 96 mm/h (normal: <20); CRP, 4.5 mg/dl (normal: <0.3); and serum albumin level, 2.8 g/dl (normal: 4.0–5.3). He was first hospitalized in the Department of Internal Medicine II of Fukushima Medical University Hospital in June 1998 because of pulmonary tuberculosis, and MTX administration was stopped. A roentgenogram and CT scan revealed lesions of pulmonary tuberculosis and a preexisting IP, as shown in Fig. 2A and B, respectively. The concentrations of serum KL-6 and SP-D on admission were 576 U/ml (normal: <500) and 53.9 ng/ml (normal: <110), respectively. He was discharged from the hospital in October 1998, showing improvement of the tuberculosis.

He complained of severe polyarthralgia with aggravation of RA afterwards, therefore, we readministered 5.0 mg/week of MTX in August 1999 at his request since he was completely cured of tuberculosis. He was hospitalized again in January 2000 to investigate the cause of fever, dry cough, shortness of breath and general malaise which started one week prior to the second admission.

The roentgenogram and CT scan revealed pneumonitis, as shown in Fig. 2C and D. The cumulative amount of MTX he received was 380 mg. The roentgenogram of the lung taken in December 1999 is shown in Fig. 2E. Retrospectively, the interstitial pneumonitis had already been apparent as shown in this figure. The representative laboratory data on admission were as follows: serum KL-6, 1,100 U/ml; serum SP-D, 298 ng/ml; CRP, 18.2 mg/dl; LDH, 639 IU/l (normal: 250–410); BUN,

![Figure 1. Clinical course of Patient 1. This patient suffered from RA since 1995 and was undergoing treatment with a 2.5 to 5 mg/day weekly pulse of MTX. He was hospitalized in 1998 because of lung tuberculosis, and MTX administration was stopped (first admission). The concentrations of serum KL-6 and SP-D on admission were 576 U/ml (normal: <500) and 53.9 ng/ml (normal: <110), respectively. MTX was readministered in 1999 and he was hospitalized again in 2000 because of MTX pneumonitis (second admission). The concentrations of serum KL-6 and SP-D increased to 1,100 U/ml and 298 ng/ml, respectively. Methylprednisolone pulse therapy (1,000 mg/day×3 days) was initiated and the concentrations of serum KL-6 and SP-D decreased to 687 U/ml and 82.2 ng/ml, respectively.](image-url)
Figure 2. The roentgenograms and CT scans of Patient 1. The roentgenogram and CT scan taken in 1998 reveal a pulmonary tuberculosis lesion in the left upper lung field and a preexisting interstitial pneumonia in the lower, posterior field of both lungs as shown in (A) and (B), respectively. The roentgenogram and CT scan taken in 2000 reveal widespread interstitial pneumonia in both lung fields as shown in (C) and (D). The roentgenogram of the lung taken in December 1999 discloses that the interstitial pneumonia is already present as shown in (E).
Miyata et al

15.1 mg/ml (normal: 9–20); creatinine, 1.3 mg/dl (normal: 0.5–1.0); PaO₂, 41.4 mmHg; and PaCO₂, 27.3 mmHg.

The patient was diagnosed as having MTX pneumonitis under the revised diagnostic criteria for adverse pulmonary events associated with MTX treatment of RA (13), and methylprednisolone pulse therapy (1,000 mg/day×3 days) was initiated. The concentrations of serum KL-6 and SP-D decreased to 687 U/ml and 82.2 ng/ml, respectively after one month along with an improvement of dyspnea and roentgenographic findings. However, the pneumonitis shadow was not completely resolved as determined by roentgenography at the end of March (data not shown).

**Patient 2**

A 64-year-old woman suffering from RA since 1988 was undergoing treatment with gold salt followed by a 5 mg/day weekly pulse of MTX since March, 1999, as shown in Fig. 3.

She was on a special diet because of diabetes mellitus and chronic renal failure. The representative laboratory data when weekly pulse of MTX was initiated were as follows: erythrocyte sedimentation rate, 105 mm/h; CRP, 4.7 mg/dl; serum albumin level, 3.6 g/dl; fasting blood sugar, 195 mg/dl (normal: <110); HB-A, 8.3 % (4.3–5.8); BUN, 35 mg/ml (normal: 9–20); and creatinine, 2.1 mg/dl (0.5–1.0). She was first hospitalized in May 1999 in the Department of Internal Medicine II of Fukushima Medical University Hospital for the investigation of an abnormal lesion in the right middle lung field, as shown in Fig. 4A. Roentgenogram, CT scan and cytology of the tumorous lesion revealed that the lesion was most likely a pulmonary adenocarcinoma; therefore, we recommended that she undergo an operation for this pulmonary tumor, but she refused because she was also suffering from chronic renal failure since 1996, possibly due to the preexisting diabetes mellitus or previous gold salt therapy.

Figure 3. Clinical course of Patient 2. This patient suffered from RA since 1988 and was undergoing treatment with a 5 mg/day weekly pulse of MTX since March 1999. She was hospitalized in May 1999 to investigate malignancy of an abnormal shadow in the right middle lung field (first admission). She was hospitalized again in 1999 because of MTX pneumonitis (second admission). The concentrations of serum KL-6 and SP-D increased to 1,270 U/ml (normal: <550) and 239 ng/ml (normal: <110), respectively. Methylprednisolone pulse therapy (1,000 mg/day×3 days) was initiated and the concentrations of serum KL-6 and SP-D decreased to 677 U/ml and 44.0 ng/ml, respectively. However, the concentration of serum KL-6 later increased again to 965 U/ml, but not that of SP-D.
Figure 4. The roentgenograms of Patient 2. The roentgenogram taken in May 1999 reveals an abnormal lesion in the right middle lung field as indicated by arrows in (A). The roentgenogram taken in October 1999 reveals widespread interstitial pneumonia in both lung fields as shown in (B). The roentgenogram taken recently reveals the apparent accumulation of the vascular marking, although there is no change in the size of the pulmonary tumor as shown in (C).

She was hospitalized again in October 1999, to investigate the cause of fever, dry cough, shortness of breath and nausea which started 3 days prior to the second admission. The representative laboratory data on admission were as follows: serum KL-6, 1,270 U/ml (normal: <500); serum SP-D, 239 ng/ml (normal: <110); CRP, 6.6 mg/dl; LDH, 506 IU/l (normal: 250–410); BUN, 31 mg/ml; creatinine, 2.3 mg/dl; PaO₂, 30.6 mmHg; and PaCO₂, 23.6 mmHg. The roentgenogram revealed pneumonitis in both middle lung fields as shown in Fig. 4B. The cumulative amount of MTX she received was 140 mg.

The patient was diagnosed as having MTX pneumonitis under the revised diagnostic criteria for adverse pulmonary events associated with MTX treatment of RA (13). Methylprednisolone pulse therapy (1,000 mg/day×3 days) was initi-
Both serum KL-6 and SP-D concentrations were within normal limits before the onset of pulmonary tuberculosis in Patient 1, even though he had a preexisting IP. These data and his roentgenograms sequentially taken previously (data not shown) suggest that his IP was inactive. The serum KL-6 concentration, but not the serum SP-D concentration, increased from 273 U/ml in August 1997 to 576 U/ml in June 1998 when he suffered from pulmonary tuberculosis. The increase in the titer of KL-6 can be explained by the presence of active and widespread lesions of pulmonary tuberculosis; Inoue et al reported that serum KL-6 can be a useful marker for determining the degree and extent of pulmonary tuberculosis (19). In contrast, the serum SP-D concentration remained within the normal range.

We predicted that serum KL-6 and SP-D concentrations would increase in the case of MTX pneumonitis since representative histopathologic changes in cases with this condition are the presence of active injury in the form of type II pneumocyte hyperplasia and fibroplastic proliferation (13). As expected, both serum KL-6 and SP-D concentrations increased along with the severity of MTX pneumonitis in Patients 1 and 2; however, the magnitude of the decrease in the serum KL-6 concentration with the improvement of symptoms was smaller than that in the serum SP-D concentration as seen in Patient 1. As described above, the MTX pneumonitis in Patient 1 was not completely resolved as determined by roentgenography at the end of March; accordingly, the serum KL-6 concentration was still high (747 U/ml) although he had no respiratory complaints.

The reason for the elevation of serum KL-6 concentration recently seen in Patient 2 could be explained by the presence of the pulmonary lesion which is most likely a pulmonary adenocarcinoma, since an elevated serum KL-6 concentration is frequently observed in patients with pulmonary adenocarcinoma [52% (17/33)] (11).

Both KL-6 and SP-D are secreted by type II pneumocytes, but their biochemical properties differ. KL-6 has biochemical properties functioning as a chemotactic factor for most fibroblasts, and increased KL-6 concentrations in the epithelial lining fluid in small airways may cause intra-alveolar fibrosis in pulmonary diseases (20). In contrast, SP-D interacts with type II pneumocytes as well as with macrophages, resulting in enhancement of phagocytosis of a wide spectrum of microorganisms (21). From these observations, it can be speculated that serum concentrations of KL-6 and SP-D may be implicated in the pulmonary fibrosis and in the activation of macrophages, respectively.

Only one study comparing the significance of serum concentrations of KL-6 and SP-D was published. It demonstrated the superiority of serum KL-6 to serum SP-D in terms of sensitivity for detection of IP and, conversely, serum SP-D may be more specific to IP than serum KL-6 (22). Either concentration, serum KL-6 or SP-D, can be used to evaluate the disease activity of IP. However, we found that serum KL-6, but not serum SP-D concentration, was elevated in cases of pulmonary tuberculosis and pulmonary adenocarcinoma, confirming previous reports (11, 19) and arguing for the specificity of SP-

Discussion

Both Patients 1 and 2 exhibited strong risk factors for MTX pneumonitis proposed by Alarcon et al (3) such as old age (≥60 years old), previous use of disease-modifying antirheumatic drugs, and hypoalbuminemia (<3.9 g/dl). Moreover, Patient 1 had a preexisting IP and Patient 2 had diabetes mellitus as additional risk factors.

It is necessary to evaluate the activity of preexisting IP in prescribing MTX to RA patients. To evaluate and monitor the activities of the IP, chest roentgenogram, CT scan, lung function testing, gallium-67 lung scan, and bronchoalveolar lavage have been clinically used (14). However, there are problems regarding the sensitivity, effort-dependability, and ease of repetition of these examinations.

KL-6 is a glycoprotein antigen expressed mainly on type II pneumocytes and respiratory bronchiolar epithelial cells (7). The serum concentration of KL-6 was elevated in the majority of patients with interstitial pulmonary disease, including idiopathic IP, IP associated with collagen vascular diseases and hypersensitivity pneumonitis (10). The concentrations of serum KL-6 are significantly higher in patients with active lung disease than in those with inactive lung disease. For example, elevation of serum KL-6 concentration was detected in 88.9% of RA patients with active IP but in only 0.6% of those with inactive IP (15). It was demonstrated that concentrations of serum KL-6 may be dependent on alveolar-capillary permeability (16); moreover, proinflammatory cytokines such as tumor necrosis factor and interferon-γ can augment the expression of KL-6 on type II pneumocytes (17). Corticosteroid inhibits proinflammatory cytokine production and secondarily reduces KL-6 production. Corticosteroid further decreases alveolar-capillary permeability caused by inflammation, resulting in a decrease in the leakage of KL-6 from the lung to the blood stream.

Alveolar surfactants, classified into surfactant proteins A (SP-A), SP-B, SP-C and SP-D, synthesized and secreted into the fluid layer by alveolar type II pneumocytes cover the alveolar epithelium. The concentration of serum SP-D is a valuable marker to detect active IP since it is elevated in accordance with proliferation of type II pneumocytes and destruction of the basement membrane of alveolar structures in patients with IP (18).

Both serum KL-6 and SP-D concentrations were within
D to IP. The magnitude of the decrease in serum KL-6 concentration in response to the treatment for MTX pneumonitis was small compared with that of serum SP-D.

This study involved only two patients. However, these markers appear quite useful based on this study and previous studies (10, 15) considering that the MTX pneumonitis is sometimes fatal, even though MTX treatment is already standardized in RA therapy. Moreover, a recent prospective study reported that the occurrence of MTX pneumonitis could not be predicted by periodic pulmonary function testing (23). Therefore, we venture to draw the following conclusion on the significance of monitoring serum KL-6 and SP-D concentrations: Monitoring of serum concentrations of KL-6 and SP-D is valuable in detecting the occurrence of MTX pneumonitis, even in RA patients with preexisting IP, and in detecting the therapeutic response of MTX pneumonitis.

Parenchymal cell damage, such as that of type II pneumocytes, precedes fibrotic changes in the interstitium of patients with MTX pneumonitis; therefore, serum KL-6 and SP-D concentrations could be elevated prior to detection by pulmonary function testing, roentgenography and CT. Further prospective studies are required to determine whether or not these serum markers are useful in predicting the onset of MTX pneumonitis.
