Abstract

Tonsillar tuberculosis is one of the uncommon forms of extrapulmonary tuberculosis. We report a case of tonsillar tuberculosis associated with pulmonary and laryngeal foci. A 23-year-old female was admitted for evaluation of hoarseness and difficulty in swallowing. Bilateral palatine tonsils were enlarged, and a tonsillectomy was performed. Since a histological study revealed tonsillar tuberculosis, antituberculous agents were administered. After the treatment the pulmonary lesions detected with chest computed tomography were improved, and her symptoms were relieved. The possibility of tonsillar tuberculosis should be considered when unexplained enlarged tonsil is observed in patients with pulmonary tuberculosis.

Case Report

A previously well 23-year-old woman was admitted on May 24, 1999 to the Department of Internal Medicine at NTT West Tokai Hospital for evaluation of hoarseness and difficulty in swallowing of two months’ duration.

There were no relevant family or past medical histories. The patient never smoked and seldom drank alcoholic beverages. On admission, her height and weight were 160 cm and 49 kg, respectively, her body temperature was 36.5 °C, her pulse was 70 beats/min, and her blood pressure was 102/64 mmHg. The head, lungs, heart, and abdomen appeared grossly normal.

Laboratory findings on admission were as follows: hematocrit 37.6%; white blood cell count 3,750/mm³; platelet count 24.4×10⁴/mm³; serum total protein 7.7 g/dl; serum aspartate aminotransferase 15 IU/l; serum alanine aminotransferase 10 IU/l; lactic dehydrogenase 240 IU/l; total bilirubin 0.5 mg/dl; serum alkaline phosphatase 151 IU/l; C-reactive protein 0.1 mg/dl; and erythrocyte sedimentation rate 9 mm in the 1st hour.

Purified protein derivative skin test was negative, and smears and cultures of sputum were also negative for acid-fast bacilli, including the testing with polymerase chain reaction (PCR). Human immunodeficiency virus (HIV) tested by enzyme linked immunosorbent assay (ELISA) was negative. Oral examination revealed the enlargement of bilateral palatine tonsils, and laryngoscopy revealed the presence of edema in the epiglottis.

For editorial comment, see p 606.
Tonsillar Tuberculosis

Figure 1. Histological findings of the resected tonsils (HE stain, ×100). Granuloma formation with epithelioid cells and Langhans’ giant cells, lymphocytic infiltration and caseous necrosis were observed.

Figure 2. Chest X-ray showed no abnormalities.

Although chest X-ray showed no abnormalities (Fig. 2), chest computed tomography (CT) showed infiltrative shadows in the middle lobe of the right lung, and in the lower lobe (S6, S9, S10) of both lungs, which were compatible with pulmonary involvement of tuberculosis (Fig. 3). Based on these findings of histological examination, chest CT, and laryngoscopy, a diagnosis of tonsillar tuberculosis associated with pulmonary and laryngeal lesions was made. Administration of antituberculous agents (isoniazid 400 mg/day, rifampicin 450 mg/day, pyrazinamide 1,500 mg/day, and streptomycin 1,000 mg/day) was given without any side effect. After the initial four weeks treatment, chest CT and laryngoscopy revealed the improvement of the infiltrative shadows in the lung field and the edema in the epiglottis, respectively. Also, the symptoms of the patient were relieved after the treatment. The patient has been free of recurrence after the completion of treatment on January 4, 2000.

Discussion

Although the improvement of lifestyle and medical and pharmaceutical advances has dramatically decreased the number of tuberculosis cases, it has still been one of the major infectious diseases all over the world, including Japan. Tonsillar tuberculosis is a rare disease recently. Tuberculosis of the oral cavity has shown a decline in several parts of the world, concomitant with the decreasing incidence of pulmonary tuberculosis. This has been attributed to the advent of specific chemotherapy to combat tuberculosis, improved surveillance, early and effective treatment and decreased infectivity (2). Also, the upper respiratory tract is generally resistant to tuberculosis (3). The presence of saliva and saprophytes, the antagonism of the striated musculature, and the thickness of the protective epithelial layer are thought to have an inhibitory effect on tubercle bacilli (3, 4).

The recent increase in the cases with HIV infection has led to a resurgence of tuberculosis. Concomitant HIV infections are present in 25% of patients with laryngeal tuberculosis (5). The present case had no history of HIV infection, and HIV tested by ELISA was negative. The commonest local symptoms of tonsillar tuberculosis are hoarseness and difficulty in swallowing (2), both of which were seen in our case.

Histological examination and the identification of tubercle bacilli usually provide the most conclusive evidence for the diagnosis (2). In the present case, the histological findings of the resected tonsils confirmed the diagnosis of tonsillar tuberculosis. The infiltrative shadows in both lungs detected by chest
CT and the edema in the epiglottis shown by laryngoscopy suggested the complication with pulmonary and laryngeal tuberculosis, respectively. Also, the improvement of the findings of chest CT and laryngoscopy after the administration of anti-tuberculous agents confirmed the presence of pulmonary and laryngeal tuberculosis. Since most of tuberculosis of the oral cavity is secondary tuberculosis originating from pulmonary tuberculosis (6), our case is thought to be a case of secondary tonsillar and laryngeal tuberculosis with primary pulmonary tuberculosis. Because of the histological evidence of the tonsils, we would emphasize tonsillar tuberculosis.

In summary, we have presented a rare case of tonsillar tuberculosis associated with pulmonary and laryngeal foci. Tonsillar tuberculosis should be considered as well as malignancy, when enlargement of the palatine tonsils is observed. Chest CT should be performed, even when chest X-ray shows no abnormalities in patients who have tonsillar tuberculosis.
