Abstract: Web searchers often use a Web search engine to find a way or means to achieve his/her goal. For example, a user intending to solve his/her sleeping problem, the query “sleeping pills” may be used. However, there may be another solution to achieve the same goal, such as “have a cup of hot milk” or “stroll before bedtime.” The problem is that the user may not be aware that these solutions exist. Thus, he/she will probably choose to take a sleeping pill without considering these solutions. In this study, we define and tackle the alternative action mining problem. In particular, we attempt to develop a method for mining alternative actions for a given query. We define alternative actions as actions which share the same goal and define the alternative action mining problem as similar in the search result diversification. To tackle the problem, we propose leveraging a community Q&A (cQA) corpus for mining alternative actions. The cQA corpus can be seen as an archival dataset comprising dialogues between questioners, who want to know the solutions to their problem, and respondents, who suggest different solutions. We propose a method to compute how well two actions can be alternative actions by using a question-answer structure in a cQA corpus. Our method builds a question-action bipartite graph and recursively computes how well two actions can be alternative actions. We conducted experiments to investigate the effectiveness of our method using two newly built test collections, each containing 50 queries. The experimental results indicated that, for Japanese test collection, our proposed method significantly outperformed two types of baselines, one used the conventional query suggestions and the other extracted alternative-actions from the Web documents, in terms of D#-nDCG@8. Also, for English test collection, our method significantly outperformed the baseline using the conventional query suggestions in terms of D#-nDCG@8.

Keywords: community Q&A, task-oriented search, query suggestion

1. Introduction

Web searchers often use a Web search engine to find a way or means to achieve his/her real-world goal. For example, a user who is suffering from a sleeping problem may issue the query “sleeping pills,” intending to find a good sleeping pill to solve his/her sleeping problem. According to a survey on 1,000 Web searchers, reported by Nakamura et al. [19], approximately 57.5% of the users answered that one motivation for using Web search engines is to find a way or means to solve their goal. Such Web search has more recently started being referred to as task-oriented search [34], and many researchers have started tackling the problem of supporting task-oriented Web search, including the TREC Tasks track [35] and NTCIR IMine TaskMine subtask [17].

In task-oriented search, the searcher faces the problem that he/she may not be aware of another existing solution that could help achieve the same goal behind the query. For example, for the searcher issuing the query “sleeping pills,” other solutions such as “have a cup of hot milk” or “stroll before bedtime” exist as well, which can also help resolve the “solve his/her sleeping problem.” Since the searcher often believes in the mean he/she initially comes up with, he/she may decide to take a sleeping pill without considering the other solutions that can solve the same problem. Although the current search engines provide query suggestions for supporting a searcher to reformulate his/her query, it is hard for the searcher to find alternative solutions.

In this study, we tackle the alternative action mining problem, where a system is required to find alternative actions for a given query. An alternative action for a query is defined as an action that can solve the same problem (See Section 3.2). For example, given the query “sleeping pills,” our objective is to find alternative actions such as “have a cup of hot milk” or “stroll before bedtime,” both these alternative actions can achieve the same goal behind the query, i.e., “solve the sleeping problem.” Mediated alternative actions can be utilized for supporting a searcher in a task-oriented Web search. For example, by suggesting the alternative actions to the searcher issuing the query “sleeping pills,” he/she is able to notice different solutions and make an improved decision on how to solve his/her sleeping problem.

We think that suggesting alternative-actions to a searcher is important in two situations. First is a situation in which a searcher lacks the enough knowledge about the problem and only knows a few specific solutions. For such a searcher, providing the alternative-solutions may help her new knowledge about the problem and an opportunity to explore diverse solutions before making a decision on choosing an actual solution to solve her problem. Second is a situation where a searcher already has the
strong belief about the solution and does not consider the possibility of the other solutions even though she knows the existence of the other solutions. For example, a user may issue the query “sleeping pills” because she strongly believes that using sleeping pills is effective for solving the problem even though she knows that other solutions such as “stroll before bedtime” or “have a cup of hot milk” might solve the problem. We think that, by suggesting alternative-actions to her, we may raise her awareness of the existence of the other solutions and encourage her to explore the other solutions instead of the solution she believed.

To tackle the alternative action mining problem, we propose leveraging a community Q&A (cQA) corpus. CQA services like Yahoo! Answers*1 or Baidu Zhidao*2 are widely used by people for solving their problems by communicating with other users. We hypothesize that the cQA corpus can be seen as an archival dataset comprising dialogues between questioners, who want to know the solutions to their problem, and respondents, who suggest good solutions for it. Figure 1 shows an example of a question-answer pair in a cQA corpus. The fundamental idea of using a cQA corpus is that, as can be seen in the figure, the two actions “take a sleeping pills” and “stroll before bedtime” are proposed by the respondents to satisfy the same goal of a questioner, which means “take a sleeping pills” and “stroll before bedtime” can be alternative actions. We also propose a method for computing how well two actions can be alternative actions using the question-answer structure of a cQA corpus. Our method constructs a question-action bipartite graph from a set of question-answer pairs and recursively computes how well two actions can be alternative actions (See Section 4).

We prepared two test collections, each containing 50 queries, for our evaluation. The experimental results using the test collections showed that our method outperformed the conventional query suggestions provided by the commercial search engines in terms of D@nDCG.

The main contributions of this study are as follows:

- We identified and defined the alternative action mining problem. We defined the problem in terms of search result diversification, and provided the definitions regarding the problem to make our work reliable (See Section 3). To our knowledge, our work is the first to address this problem.
- We proposed utilizing the cQA corpus to address the problem. We revealed that the questions-answer relationship can be effective for identifying how well two actions can be alternative actions.
- We prepared the test collections for the alternative action mining problem. Our two test collections, each of which contains 50 queries, are constructed from two different services, which enabling us to investigate the applicability of our method (See Section 5).

The rest of this study is organized as follows. Previous studies related to our study are introduced in Section 2. The alternative action mining problem addressed in this study is defined in Section 3, as well as the definitions of related concepts. Our approach to mining alternative actions from a cQA corpus is explained in Section 4. The evaluation methodology is described in Section 5, and the results are reported in Section 6. Finally, the study limitations are discussed in Section 7, and Section 8 concludes the study.

2. Related Work

2.1 Task-Oriented Web Search

Hassan et al. studied on supporting the complex search task, in which a searcher has to accomplish several subtasks to satisfy his/her information need [10], [11]. They proposed a method that includes grouping queries into the same task through the query log mining and query syntactic analysis. Wang et al. proposed a method for extracting task names from the microblog corpus for supporting the complex search task [26]. Jones and Klinkner proposed the mission-goal hierarchical relationship [14] between information needs, and proposed a method for classifying a pair of queries into the same mission/goal (referred to as task in their study) or not. Aiello et al. also proposed a clustering algorithm that clusters missions into underlying topics [2]. Although, in the present study, a hierarchical relation is assumed between actions as in these previous studies; our study focuses on the users’ real-world behavior rather than on other types of searches such as covering many aspects of a topic.

The studies that are most relevant to the present study are those by Yamamoto et al. [31] and Yang et al. [34]. Yamamoto et al. defined the goal-subgoal relationship and proposed a method for clustering queries into subgoals by leveraging the sponsored search data. Yang et al. defined the task-subtask relationship and proposed a method for connecting search queries with task descriptions written in wikiHow*3. Although they used the different terminologies for defining the hierarchical relationship, both definitions were based on the is-achieved-by relationship. In this study, we also use the is-achieved-by relation to define alternative actions. Recently, TREC and NTCIR attempted to tackle the task-oriented Web search [17], [35]. For example, in the TaskMine subtask of the NTCIR-11 IMine task, a system was asked to retrieve a set of subtasks for a given task.

The key difference between the above studies and ours is that most of the existing studies focused on finding sub tasks for a given query. For example, given the query “lose weight,” the desired outputs are “do physical exercise” and “control calorie intake,” each of which can achieve the query [17]. On the other hand, we attempt to find alternatives to a given query (See Sec-

*1 https://answers.yahoo.com/
*2 https://zhidao.baidu.com/
*3 http://wikihow.com
tion 3.3). This enables us to suggest a searcher with other solutions for solving his goal, which has not been addressed by the existing work.

2.2 Connecting cQA with Web Search

Recent studies indicated that a cQA corpus can be used to improve the performance of a Web search. Omari et al. [21] proposed a method for ranking answers of a cQA corpus based on their novelty, in order to improve Web search by displaying the answer in SERP. Yamamoto et al. [30] used a cQA corpus as a resource for extracting adjective facets and use them as query suggestions to support Web searchers.

Liu et al. [17] extensively analyzed the behavior logs obtained from a Web search engine and a cQA service, and revealed the typical patterns when a Web searcher gives up his/her search and asks a question in the cQA service. According to their study, a searcher who issues a query containing terms such as “how,” “can,” or “do,” etc., tended to ask a question. Another study showed that one popular type of questions on a cQA service is a how-to question [9]. With regard to these studies, Weber et al. focused on a Web search query related to how-to information, and proposed a method for extracting its answer from the cQA corpus [27]. These results suggest that a cQA corpus contains much how-to information, which can be effectively used for mining alternative actions.

2.3 Comparative Entity Mining

Suggesting alternative actions to a searcher may allow his/her to compare several solutions for making an appropriate decision. Some researchers tackled the problem of finding comparative entities from the data. Jindal and Liu studied on identifying comparative sentences in a text corpus [13]. Li et al. [16] extended their work and proposed a method to extract comparative entities from the questions in Yahoo! Answers. Tsukada et al. [25] proposed a method to extract co-ordinate entities, which share one or more common hypernyms with a given query by using the hypernym-hyponym dictionary. The focuses of the above work were on finding comparative entities (e.g., “iPod” and “PSP” [16] or “Cristiano Ronaldo” and “Lionel Messi” [25]), whereas our work deals with actions (e.g., “take a sleeping pill” and “stroll before bedtime”). For some task-oriented searches, suggesting comparative entities are firmly beneficial to a searcher since he/she can find another solution to achieve his/her goal. However, as in the example of “sleeping pills” mentioned in Section 1, there are task-oriented searches that cannot be wholly solved by suggesting the comparative entities.

3. Problem Definition

In this section, we define the alternative action mining problem addressed by the present study. As discussed in the literature [11], [34], different terminologies were used in many of the exiting studies to represent similar concepts, such as mission-goal [14], goal-subgoal [31] or task-subtask [11], [34]. In this study, we basically follow the definitions proposed by Yang et al. [34], except that the use of the term action instead of using task. This is done because we focus on a verbal phrase as our retrieval unit.

We first introduce several concepts including the concepts of the action, the is-achieved-by relationship and the alternative actions relationship. We then define the alternative action mining problem. Finally, we discuss the relation of our study to the existing studies.

3.1 Alternative Action

Definition 1 (action): An action is an activity that a user wants to achieve. In our study, we represent an action as a verbal phrase, as in the work [31]. For example, “take a sleeping pill,” “have a cup of hot milk,” and “solve one’s sleeping problem” are actions.

Definition 2 (is-achieved-by relationship): For two actions \( a_i \) and \( a_e \), we call \( a_i \) is-achieved-by \( a_e \) when achieving \( a_i \) helps to achieve \( a_e \). Figure 2 illustrates the example actions for the is-achieved-by relationship. In the figure, action \( a_g \) is achieved by \( a_i \) after achieving \( a_g \) helps to achieve “solve one’s sleeping problem.” For the convenience, in this study, we also call “action \( a_i \) is a goal of \( a_e \),” whose meaning is “\( a_i \) is-achieved-by \( a_e \).”

Definition 3 (alternative actions relationship): For two actions \( a_i \) and \( a_j \), we call \( a_i \) and \( a_j \) are alternative actions when they are different actions and there exists at least one other action \( a_g \) which is their common goal.

As shown in Fig. 2, the actions “take a sleeping pill” and “stroll before bedtime” are alternative actions since they share the same goal “solve one’s sleeping problem.” Also, note that, actions “take a sleeping pill” and “drink chamomile tea” are also alternative actions since they share the other goal “cure one’s anxiety.”

3.2 Alternative Action Mining Problem

As introduced in Section 1, our objective is to automatically mine alternative actions for a given query. One thing we have to consider is the ambiguity of the goals behind the query. As shown in Fig. 2, the action “take a sleeping pill” can be used to achieve two different goals. Thus, for a searcher who issues the query “sleeping pills,” it is hard to predict which goal the searcher wants to achieve, i.e., “solve his/her sleeping problem” or “cure his/her anxiety,” and the desired alternative actions depend on it. To solve this ambiguity, we follow an approach similar to the one used in the search result diversification [1], [5], [17], [29], where, for a given query, the system is required to generate a diversified ranked list of documents satisfying as many different search intents behind the query as possible. The alternative action mining
problem is defined as follows:

**Alternative action mining problem:** Given a query \( q \), the alternative action mining problem refers to returning a diversified ranked list of \( k \) alternative actions \( a_1, a_2, \ldots, a_k \) for that query, which can satisfy as many different goals of searchers who issue \( q \).

Note that in this study we do not limit our query as a verbal phrase, and accept any form of a query as an input of our method. In this work, we assume that any query issued by a searcher implies its corresponding action. For example, for the query “sleeping pills,” we assume that the implied action for the query is “take sleeping pills.” So, for the query “sleeping pills,” our objective is to automatically generate a ranked list of actions (e.g., “stroll before bedtime,” “drink chamomile tea”), which can satisfy two different goals “solve one’s sleeping problem” and “cure one’s anxiety,” of the action implied by the query “sleeping pills.” The reason why we accept all forms of queries is that we think people may not use a verbal phrase such as “take sleeping pills” as a query when using a Web search engine and noun queries such as “sleeping pills” is much popular. Note that while our method accepts any forms of queries, its outputs (i.e., alternative-actions) are the form of the verbal phrase.

### 3.3 Relation to Existing Work

To clarify our problem, Fig. 3 illustrates the relation of our problem to the existing work [17], [31], [34], [35] in task-oriented Web search. As can be seen in the figure, most existing studies addressed the problem of finding sub-tasks (or sub-goals) of a given query. For example, given the query “sleeping problem,” many of the existing studies were focused on finding “take a sleeping pill” or “stroll before bedtime,” both of which can achieve the goal behind the query “solve one’s sleeping problem.” Such work can be seen as a method for supporting searchers to find more concrete solutions for achieving the action represented by the query.

In contrast, our study is different from these previous studies in a way that ours is to help searchers to find alternative solutions for the goals behind the query. We believe that our study provides another type of supports for a searcher in a task-oriented Web search and is as important as the existing studies.

### 4. Our Approach

In the previous section we defined the alternative mining problem addressed by this study. In this section we explain our proposed method, which utilizes a cQA corpus to automatically find alternative actions to a given query. We first discuss a technical challenge of the problem. We then give the details of the proposed method.

---

**Fig. 3** Comparison between existing work [17], [31], [34], [35] and our study. Most existing studies addressed the problem of finding sub-actions, whereas our study finds alternative ones.

**Fig. 4** Method overview.
sifted ranked list of alternative actions for the query.

4.3 Retrieve Question-Answer Pairs

Given a query $q$, we first retrieve a set of question-answer pairs from a CQA corpus. We hypothesize that some questions are likely to receive many suggestions by the respondents because of their content. For example, when a question contains “Should I use sleeping pills?” in its text, its answers will likely to contain many actions other than “take a sleeping pill” because the questioner is unsure about his/her idea. Thus, retrieving such questions may help us find alternative actions from their answers.

To this end, we manually prepare some terms that are likely to indicate that a questioner is unsure about his/her idea. Table 1 lists up the terms we prepared. By using these terms we retrieve questions and answers related to the query. More specifically, we first retrieve answers containing $q$. We then obtain the questions from these answers. Next, we rank the questions by using the terms show in Table 1 by the Okapi BM25 algorithm and obtain the top $n$ questions ($n = 10,000$ in our experiments). Finally, we retrieve all the answers of these questions, and obtain a set of question-answer pairs for the $n$ questions.

4.4 Extract Candidate Actions from Answers

After we obtain the set of question-answer pairs, we extract candidate actions from their answers. We extract all the verbal phrases from the answers. We apply the standard text-chunking approach using Conditional Random Field (CRF) to extract verbal phrases from the answers. We prepare 500 sentences by sampling answers in the CQA corpus, and annotate the verbal phrases in the sentences. We then learned the classifier which classifies terms in a sentence into a verbal phrase or not. We use the standard 19 features for text chunking [20] including bag-of-words and parts-of-speech of the target word and its surroundings. We apply the learnt classifier to the texts of the answers and extract a set of actions.

In this step, different verbal phrases are treated as different actions even though they are semantically similar. For example, when CRF outputs “do exercise” and “do exercise everyday” from the answers, we regard that we obtain two different actions “do exercise” and “do exercise everyday.” Also, when CRF outputs two identical verbal phrases “do exercise” and “do exercise” from the answers, we regard that we obtain one action “do exercise.” We expect that semantically similar actions such as “do exercise” and “do exercise everyday” can be removed by applying the MMR algorithm described in Section 4.7.

4.5 Measure Alternativeness between Actions

Obtaining the set of actions from the previous step, we compute the alternativeness between actions. As we mentioned in Section 4.1, it is hard to compute the alternativeness between two actions simply using the usual textual or semantic similarity. To compute the alternativeness between two actions we make the following two hypotheses:

- **H1 (question → action):** If two questions are likely to represent the same goal, actions in their answers are likely to be alternative actions.
- **H2 (action → question):** If two actions are likely to be alternative actions, questions of the answers containing these actions are likely to represent the same goal.

Take, as an example, two different questions “I am suffering from my sleeping problem. What should I do?” and “How can I sleep well?” We can expect that answers to these different questions are intended to satisfy the same goal, which we can obtain H1. Also, for two answers containing the different actions “take a sleeping pill” and “have a cup of hot milk,” we can expect that the questions are likely to address the same problem, which we can obtain H2.

Since H1 and H2 are recursive – the alternativeness between two actions depends on how likely two questions represent the same goal, and this depends on the alternativeness between actions in their answers – we apply the SimRank algorithm [12], which is designed to compute the similarity between nodes on a graph, on the question-action bipartite graph. We first prepare the question-action bipartite graph from the questions and actions extracted in the previous steps (shown in Fig. 5). Let $Q = \{Q_i\}_{i=1}^n$ be the set of questions retrieved by the step described in Section 4.3, $A = \{a_j\}_{j=1}^m$ be the set of actions extracted in the step described in Section 4.4, and $\mathcal{A} = A \cup \{q\}$ be the union of these actions and query, we construct a bipartite graph $G = (Q \cup \mathcal{A}, E)$, where $E \subseteq Q \times \mathcal{A}$ and edge $e_{ij} = (Q_i, a_j) \in E$ in $G$ represents that action $a_j$ appears in at least one answer of question $Q_i$.

Let $\text{sim}_\text{goal}(Q_i, Q_j)(Q_i, Q_j \in Q)$ represent how well two questions represent the same goal, and $\text{alt}(a_i, a_j)(a_i, a_j \in \mathcal{A})$ represent how well two actions are alternative actions. If $Q_i = Q_j$, the initial value for $\text{sim}_\text{goal}(Q_i, Q_j)$ is set to 1, otherwise the initial value for $\text{sim}_\text{goal}(Q_i, Q_j)$ is 0. We use the same condition to initialize the value for $\text{alt}(a_i, a_j)$. After we assign the initial values to $\text{sim}_\text{goal}(\cdot, \cdot)$ and $\text{alt}(\cdot, \cdot)$, we update these two measures by iteratively computing the following two formulae:

$$\text{sim}_\text{goal}(Q_i, Q_j) = \frac{C}{|Q_i|} \sum_{l=1}^{|Q_j|} \sum_{k=1}^{|Q_l|} \text{sim}_\text{goal}(O_l(Q_i), O_l(Q_j)),$$

$$\text{alt}(a_i, a_j) = \frac{C}{|I(a_i)|} \sum_{l=1}^{|I(a_j)|} \sum_{k=1}^{|I_l(a_j)|} \text{sim}_\text{goal}(I_l(a_i), I_l(a_j)),$$  

where $C$ is a constant value and $O(Q_i) \subseteq \mathcal{A}$ is a set of out-neighbors of $Q_i$, and $I(a_i) \subseteq Q$ is a set of in-neighbors of $a_i$. We use $C = 0.8$ and the values of $\text{alt}(\cdot, \cdot)$ obtained after the five-itera-
tions, as suggested in Ref. [12].

From the alternativeness between query $q$ and action $a_i$, $\text{alt}(q, a_i)$, we can know that how well an action $a_i$ can be the alternative actions for a query $q$, which is used to determine the relevance of the action to the query. Moreover, the alternativeness between two actions $\text{alt}(a_i, a_j)$ indicates how well two actions share the same goal; high $\text{alt}(a_i, a_j)$ means they are similar in terms of their goals and low $\text{alt}(a_i, a_j)$ means they are dissimilar. This information can be used for the diversification of the ranked list.

4.6 Measure Effectiveness of Action by Community Evaluation

To improve the performance of measuring the relevance between query and action, we also propose utilizing the quality of answers evaluated by the community in the service. Most cQA services enable their users to evaluate the quality of answers by, for e.g., selecting best answers or up-voting good answers. Our idea is that such evaluations by the community can help find actions that many people believe in their effects.

We compute the effectiveness of action $a_i$, as the probability that an answer containing $a_i$ be selected as a best answer:

$$\text{effect}(a_i) = \frac{|\text{BestAnswers}(a_i)| + \theta}{|\text{Answers}(a_i)| + 2\theta},$$ (3)

where $\text{BestAnswers}(a_i)$ and $\text{Answers}(a_i)$ represent the set of best answers and answers in the question-answer pairs retrieved by the step in Section 4.3, respectively, and $\theta$ is the Laplace smoothing parameter ($\theta = 8$ in our experiments).

4.7 Generate Diversified Ranked List

Once we compute the alternativeness between actions and their effectiveness, we generate a ranked list of actions. As described in Section 3.2, the purpose of the ranked list is to achieve as many different goals behind the query as possible.

To this end, we apply the result diversification technique to diversify the ranked list. We apply the Maximal Marginal Relevance (MMR) algorithm [4] to generate the diversified ranked list of actions. MMR iteratively chooses the relevant items considering both the relevance and diversity. Letting $A = \{a_i\}_{i=1}^m$ be the set of candidate actions to be ranked, MMR selects $a'\ast$, an action ranked at the $r$-th position using:

$$a' = \arg \max_{a \in A} \left[ \lambda \cdot \text{rel}(q, a) - (1 - \lambda) \max_{a' \in S^{-1}} \text{alt}(a, a') \right],$$ (4)

where

$$\text{rel}(q, a) = \alpha \cdot \text{alt}(q, a) + (1 - \alpha) \cdot \text{effect}(a).$$ (5)

$S^{-1}$ denotes a set of $r-1$ actions that MMR has already selected. $\lambda$ is a parameter balancing the relevance and the diversity, and $\alpha$ is a parameter balancing the alternativeness and the effectiveness. By applying the MMR algorithm, we obtain the diversified ranked list of $k$ alternative actions for the query.

5. Experimental Setup

In this study, we address the following research questions by conducting the experiments: (1) Does our proposed method outperform the query suggestions provided by the commercial search engines in terms of the providing alternative actions for a query? (2) Can our method work for the cQA corpora on different services? (3) How do the parameters $\lambda$, which balance the relevancy and diversity, and $\alpha$, which combine the alternativeness and effectiveness, affect the performance? (4) For what kinds of queries does our method work effectively? We prepared two test collections for Japanese and English, which we refer to JaCollection and EnCollection.

5.1 Dataset

We use the corpus archived in Yahoo! Chiebukuro4, which is the most popular community Q&A service in Japan, for JaCollection. Table 2 shows the statistics of the Yahoo! Chiebukuro corpus we use in this evaluation. We build the search system on Elasticsearch to retrieve questions and answers from the corpus.

We also use other data in the evaluation to investigate whether our method works on different data. We use the data archived in Reddit5 as another cQA corpus for EnCollection. Reddit is one of the most popular online communities, where users communicate by making posts and giving comments to them. Although the purposes of the Reddit users are not only for community-based Q&A, in this study we view Reddit as the community Q&A service; assuming a post made by a user as a question and the comments to the post as its answers. We use the APIs6 provided by Reddit to retrieve posts and their comments.

One difference between Yahoo! Chiebukuro and Reddit, which affects our method, is that Yahoo! Chiebukuro allows users to vote for the best answer whereas Reddit does not have option. Instead, Reddit allows users to provide a positive or negative voting to a comment. Thus, when computing Eq. (3) for the Reddit data, instead of computing the best answer probability we compute the probability that a comment receives positive votes.

5.2 Proposed and Baseline Methods

To measure the effectiveness of our method, we prepare the following methods:

- **Query Suggestion (QS):** We extract the query suggestions from a Web search engine to investigate whether the current query suggestions provide alternative actions. We use the query suggestions provided by the two commercial search engines, which we refer to as QS1 and QS2, respectively. The reason why we use the query suggestions as our baselines is we expect that some of the query suggestions are “parallel move” of the query. According to the study by Boldi et al. [3], parallel move is one type of query reformulation in which a searcher reformulates her query from one

427–438 (May 2018)
aspect of a topic to something related but not equivalent (e.g., from “kyoto travel” to “osaka travel”). As query suggestions in part relying on the query log of searchers, we expected that “parallel move” query suggestions can be alternative-actions of a query.

- RelDivWeb: This is another baseline method, which extracts alternative-actions from the Web documents. First, it extracts the top 500 Web search results from the Bing Web search API\(^7\) and obtained the contents of the 500 Web documents. We used the existing Python libraries\(^8\) to extract the main contents of the Web documents. We then applied the same CRF classifier trained in Section 4.4 to extract the set of candidate actions \(A = \{a_1, \ldots, a_n\}\) from the main contents of the \(k\) Web documents. Finally, we ranked the actions by applying the MMR algorithm. MMR selects \(a'\), an action ranked at the \(r\)-th position using:

\[
d' = \arg \max_{a \in S \subseteq A} \left[ \lambda \cdot \text{rel}(q, a) + (1 - \lambda) \max_{a' \in S} \text{sim}(a, a') \right],
\]

where

\[
\text{rel}(q, a) = \frac{\text{freq}(a)}{\max_{a \in A} \text{freq}(a)},
\]

\[
\text{sim}(a, a') = \frac{|D(a) \cap D(a')|}{|D(a) \cup D(a')|}.
\]

In the above equations, freq\((a)\) represents the frequency of an action \(a\) in the top 500 Web documents, and \(D(a)\) represents the set of Web documents containing action \(a\). Since a Web document does not have the hierarchical structure like a question-answer pair in cQA, we decided to use the frequency of an action for measuring relevance and co-occurrence for measuring similarity between actions. For parameter \(\lambda\), we used the optimum value for EnCollection when evaluating JaCollection, and used the one for JaCollection when evaluating EnCollection.

- RelOnlyWeb: This is the same as RelDivWeb, except that we set \(\lambda = 1.0\). Thus, RelOnlyWeb only considers the relevance but not the diversity of the ranked list.

- RelDivQA: This is our proposed method which generates a ranked list of actions based on Eqs. (4) and (5). Equations (4) and (5) contain two parameters \(\lambda\) and \(\alpha\). To fairly compare with the baselines and our method, we use the optimum \(\lambda\) and \(\alpha\) for EnCollection when evaluating JaCollection, In addition, we use the ones for JaCollection when evaluating EnCollection. The effects of these parameters are investigated in Section 6.2.

- RelOnlyQA: This is the same as RelDivQA, except that we set \(\lambda = 1.0\). Thus, RelOnlyQA only considers the relevance but not the diversity of the ranked list.

### 5.3 Test Collection Construction

JaCollection used Yahoo! Chiebukuro and EnCollection used Reddit as the cQA corpus. We first prepare 50 queries to be used as the input to alternative action mining. We chose three domains (Health, Recreation and Education) to select queries. The reason why we chose these domains is, according to Donato et al., information needs in domains such as travel, health and education tend to be complex\([6]\). Hence, these are typical domains where it is important to show alternatives to a searcher. Note that these domains were also used in previous studies\([17], [31]\). Table 3 shows example queries we use for EnCollection. Both test collections contain 25 queries from health, 14 from recreation and 13 from education. As described in Section 3.2, our method accepts any forms of a query and does not restrict the form as a verbal phrase. We think queries shown in Table 3 are not infrequent in Web search.

We view our alternative mining problem as similar to the search result diversification. To evaluate our method, we need the following ground truth:

- A set of goals \(G_q = \{g_1^q, \ldots, g_n^q\}\) for query \(q\), where \(n\) is the number of goals for \(q\). E.g., for query “sleeping pills,” \(G = \{‘solve one’s sleeping problem’, ‘cure one’s anxiety’\}‘.
- Goal-level action relevance rel\((a, g)\), which represents how well an action \(a\) is an alternative action to the query \(q\) in terms of achieving its goal \(g\).

For preparing the set of goals for each query, an assessor is asked to search the Web to familiarize with the query, and then to write down up to three goals in a verbal phrase representation. When writing down the goals for a query, the assessor was required to prepare the goals for the action implied by the query. For example, for the query “sleeping pills,” if the assessor guessed its implied action as “take sleeping pills,” the assessor prepared the goals for the action “take sleeping pills.”

In order to prepare goal-level action relevance, three assessors for each language are used in this experiment. We first pool the results of both baseline and proposed methods at the pool depth size at 10. For the proposed method, we generate the ranked result for each combination of the two parameters \(\lambda\) and \(\alpha\), by changing their parameters from 0.1 0.2, \ldots, to 1.0. Then, for each query, an assessor was asked to annotate goal-level action relevance for the pooled actions. The annotation is conducted in the following step. For each (query, goal, action), we ask the assessors to annotate its relevance with three-graded scores according to the following criteria:

- **highly relevant (2)**: action \(a\) strongly helps to achieve goal \(g\), and also \(a\) is another solution which differs from the action represented by the query itself.
- **relevant (1)**: action \(a\) may help to achieve goal \(g\) and also \(a\) is another solution which differs from the action represented by the query itself.

#### 5.4 Evaluation Metric

We use D#-nDCG [24], which was proposed by Sakai et al. and has been used in the NTCIR INTENT [23] and IMine [17], [29] tasks. The purpose of D#-nDCG is to intuitively evaluate a ranked-list in terms of both its diversity and relevance. Given a set of goals $G^i = \{g^i_1, \ldots, g^i_m\}$, let $p(q_i)$ represent the probability that a searcher issuing $q_i$ has the goal $g^i$, for which we assumed the uniform probability $p(q_i) = \frac{1}{|G^i|}$ in our evaluation, and let $\gamma(g^i, a')$ be the goal-level gain value of the $\alpha'$ action at rank $r$ returned by a method, which is defined as $\gamma(g^i, a') = \frac{2^{|G^i|} \gamma(g^i, a') - 1}{|G^i|}$. The global gain for this $r$-th ranked action is defined as:

\[
\gamma(g^i, a') = \sum_{g^i \in G^i} p(g_i) \gamma(g^i, a') .
\]  

(9)

The ideal ranked list of actions is obtained by sorting all the pooled actions by the global gain. Let $gg^i(a')$ denote the global gain in this ideal list. D-nDCG at cutoff $k$ is defined as:

\[
D\text{-}nDCG@k = \frac{\sum_{r=1}^{k} gg^i(a')/ \log(r + 1)}{\sum_{r=1}^{k} gg^i(a')/ \log(r + 1)} .
\]  

(10)

D#-nDCG is defined as a linear combination of D-nDCG and I-rec, which measures the recall of goals covered by the ranked list.

Let $G^i \subseteq G^q$ be the set of goals covered by the top $k$ actions of the ranked list. In this work, we consider that goal $g^i$ is covered when there exists at least one action relevant to $g^i$ in the top $k$ actions. Then the recall of goals I-rec at cutoff $k$ is defined as:

\[
I\text{-}rec@k = \frac{|G^i \cap G^q|}{|G^i|} .
\]  

(11)

With D-nDCG and I-rec, D#-nDCG at cutoff $k$ is computed as:

\[
D\#\text{-}nDCG@k = \gamma I\text{-}rec@k + (1 - \gamma) D\text{-}nDCG@k ,
\]  

(12)

where we let $\gamma = 0.5$, following the NTCIR INTENT and IMine tasks. We use D#-nDCG@8 as our primary metric since many of the conventional query suggestions provide eight suggestions to a query. The ranked list containing more relevant and diverse (in terms of $q'$s goals) actions achieves higher D#-nDCG@8.

#### 6. Experimental Results

##### 6.1 Comparison with Baselines

Table 4 shows the results of D#-nDCG@k of the baseline and our methods described in Section 5.2 for two test collections. Here, for RelDivQA, we use $\alpha = 0.7$ and $\gamma = 0.6$ as parameters, which is the optimum D#-nDCG@8 for EnCollection, for evaluating JaCollection. We also use $\alpha = 0.4$ and $\gamma = 0.5$, which achieves the optimum D#-nDCG@8 for JaCollection, for evaluating EnCollection. For RelDivWeb, we used $\alpha = 0.5$ which achieves the optimum D#-nDCG@8 for EnCollection, for evaluating JaCollection. Also, since we observed that we obtained the same D#-nDCG@8 for different $\lambda$ for evaluating JaCollection, we decided to use $\lambda = 0.5$ for evaluating EnCollection.

From the table, we can see that both RelDivQA and RelOnlyQA outperform the baselines for both test collections. In addition, it can be seen that D#-nDCG of both QS1 and QS2 are quite low, compared with RelDivQA and RelOnlyQA. This result indicates that conventional query suggestions rarely provide alternative actions for a query, whereas cQA is an effective resource for mining alternative actions. Also, one possible reason why the performance of RelDivWeb was less than RelDivQA is the most Web documents retrieved by the query is so relevant to the query that the alternative-actions rarely appeared in the documents. The two-sided Randomized Tukey’s HSD test [22] revealed that, in terms of D#-nDCG@8, we observed the significant differences between all the pairs of the proposed methods and the baselines at the significant level $\alpha = 0.01$ for JaCollection. On the other hand, for EnCollection, we observed that the differences between the proposed methods and the query suggestions (QS1, QS2) were significant, while the differences between the proposed methods and the Web-based baselines (RelDivWeb, RelOnlyWeb) were not significant in terms of D#-nDCG@8. In addition, having that our methods achieved the similar perfor-

| RelDivQA        | 0.133 | 0.267 | 0.304 | 0.371 |
mance on different test collections, the experimental results suggest that our method is able to applicable to many cQA services.

When we compare the results of RelDivQA and RelOnlyQA, we observe that the results of RelDivQA and RelOnlyQA are similar. The two-sided Randomized Tukey’s HSD test revealed that the differences between RelDivQA and RelOnlyQA were not significant for all the metrics on both test collections. This implies that the combination of the relevance and diversity does not always help to improve the performance in our evaluation. One possible reason of this would be that the number of goals were small. As described in Section 5.3, each query has at most three goals, which is relatively small number compared with the existing test collection [17], [23].

### 6.2 Effect of Parameters

We evaluate D#-nDCG@8 obtained by our method by varying the parameters $\alpha$ and $\lambda = 0.1, 0.2, \ldots, 1.0$ to investigate how diversity and effectiveness affected the performance. Table 5 summarizes the results on each test collection. From the tables, we observe that the optimum parameters are $\alpha = 0.5, \lambda = 0.4$ for JaCollection (0.4142 for that condition and 0.4138 for the other cells denoting 0.414) and $\alpha = 0.6, \lambda = 0.7$ for EnCollection.

For JaCollection, as we can see from the table, we could not find the effect of changing the parameters. One possible reason of this is that our method generated the similar ranked list for different parameters. As described in Section 5.3, JaCollection contains less actions (3,899) than EnCollection does (8,125), which implies that the ranked lists for JaCollection generated by our method are similar to each other.

On the other hand, we found some trends in the results on EnCollection. The combination of alternativeness and effectiveness (e.g., $\alpha = 0.5$) improves D#-nDCG@8 as compared with the case where each was used alone (e.g., $\alpha = 0.1$ or 1.0). This result indicates that considering both alternativeness and effectiveness helps to find alternative actions for a query for EnCollection. Also, when we focus on $\alpha = 0.5$, D#-nDCG improves as we change $\lambda$ from 1.0 to 0.7, which suggests that the alternativeness between two actions $\text{alt}(a_i, a_j)$ enables a method to generate a diversified ranked list for EnCollection. As described in Section 4.5, we iteratively update $\text{sim}_{\text{goal}}(\cdot, \cdot)$, which measures how well two questions represent the same goal, and $\text{alt}(\cdot, \cdot)$, which measures how well two actions are alternative actions. We manually checked the values of $\text{sim}_{\text{goal}}(\cdot, \cdot)$ to investigate whether $\text{sim}_{\text{goal}}(\cdot, \cdot)$ actually worked for EnCollection. For example, we found that the two questions “I think I have depression. What do I do now?” and “I think my tiredness is affecting my life too much and I don’t know what to do” have high $\text{sim}_{\text{goal}}(\cdot, \cdot)$, whereas these two questions are not textually similar. This result also suggests that our method successfully computes the alternativeness between actions for EnCollection.

### 6.3 Effect of Domain

To investigate the effectiveness of our method with the different domains, Table 6 summarizes D#-nDCG@8 for three domains. Note that we used the optimum parameters for each test collection when computing D#-nDCG@8. From the table, we can observe that the results of the health domain achieved the best performance for both JaCollection and EnCollection. The possible explanation of this would be, in the health domain, people discuss about many possible solutions for solving their problems since they want to choose the effective and credible solution for their health. We thus could find many alternative actions from the cQA corpus.

### 6.4 Examples

Table 7 shows examples of the alternative actions retrieved by our method and baselines (QS1 and QS2). For example, for the query “chamomile tea,” our method successfully ranked the alternative action “drink a cup of hot milk,” which can achieve the goal behind the query “promote falling asleep” at the first rank, while the baselines QS1 and QS2 suggested the queries which specialize the input query (e.g., “chamomile tea effect”). Since the conventional query suggestions are not designed for providing alternative actions for a query, suggesting the alternative actions obtained by our method can complement the existing query suggestions and help a searcher make an improved decision on how to achieve his/her goal.

On the other hand, from the table we can see that our method ranked the action “put it on your eyes,” which seems a meaning-

less phrase, at the second rank of the query “chamomile tea.” We
found that many of the irrelevant actions retrieved by our method
were such meaningless verbal phrases, which affected the per-
formance of our method. We will discuss how to improve our method
in Section 7.

7. Limitations
Our work has several limitations that we should acknowledge.
First, we take a search result diversification approach to gener-
ating a ranked list of alternative actions. The problem of this
approach is that the ranked list contains actions which achieve
different goals and it would be difficult for a searcher to find the
alternative actions which achieve his/her actual goal. Several pos-
sible solution to solve this problem would be clustering the alter-
native actions according to their goals or predicting the goal of
the searcher by analyzing his/her behavior log.

Second, as shown in Table 4, D#-nDCG obtained by our
method is relatively low, compared with the standard search result
diversification problems [17], [23]. Currently our method just ex-
tact actions (verbal phrases) from the answers in the cQA corpus
and use them as the candidates for the ranked list. The prob-
lem is that these actions contain lots of irrelevant actions which
cannot be regarded as alternative actions for a query. This prob-
lem is caused by our candidate action classifier which extracts
too many irrelevant actions. We evaluated the performance of
CRF explained in Section 4.4 with five-fold cross-validation, and
found that its precision, recall, and F1-measure were 0.48, 0.46
and 0.47, respectively, for EnCollection. The irrelevant actions
make the performance (i.e., D#-nDCG) of our alternative-action
mining low. Some researchers proposed to use syntactic patterns
to extract target entities from a text corpus [16]. Applying such
a method would enable us to extract the candidate alternative
actions rather than actions from the cQA corpus.

Third, we have not enough considered about the correctness
of an action which might be a critical problem especially for an
action under the medical domain. In this study, we used the ef-
effectiveness of an action to use the ranking. However, a high ef-
effectiveness of an action does not guarantee that the action is cor-
correct since the effectiveness just measures a sort of popularity.
In order to solve the problem of the correctness of the mined ac-
tions, we may verify the alternative-action with the domain spe-
cific knowledge-bases such as WebMD, PubMed as the effective-
ness of actions under these knowledge-bases are guaranteed by
the domain experts.

Lastly, we should acknowledge the belief of a searcher. Peo-
ple usually favor information that confirms their pre-existing be-
liefs and biases [15]. Recently, White also revealed that the ex-
istence of the search biases in which users preferred affirmative
information to their beliefs [28]. His findings implies that, even if
we successfully provide alternative actions to a searcher, he/she
would not take them into consideration because he/she believes
in the solution expressed by the query. Although it is challenging
to change the belief of a searcher, many researchers attempted
to support a searcher’s credible or careful search, e.g., by sug-
gest disputed sentences [7], [32] or providing scores according
to credibility criteria [33]. By applying such methodologies, we
may raise the awareness of the searcher.

8. Conclusions
In this study, we addressed the alternative action mining prob-
lem. We defined the alternative mining problem as similar in
the search result diversification. To our knowledge, our work
is the first to study this problem. Also, we proposed leverag-
ing a cQA corpus to address the alternative action mining
prob.

method iteratively computes two measures; (1) alt(·, ·),
which measures the alternativeness between two actions, and
(2) simgoal(·, ·), which measures how well two questions repre-
sent the same goal, by applying the SimRank algorithm to the
question-action bipartite graph. Our method generates the diver-
sified ranked list of alternative actions by applying the MMR
algorithm according to the alternativeness between actions.

The experimental results indicated that, for Japanese test col-
lection, our proposed method significantly outperformed two
types of baselines, one used the conventional query suggestions
and the other extracted alternative-actions from the Web docu-
ments, in terms of D#-nDCG@8. Also, for English test collec-
tion, our method significantly outperformed the baseline using
the conventional query suggestions in terms of D#-nDCG@8. We
believe that our method can complement the conventional query
suggestions and help a searcher make an improved decision on
how to achieve his/her goal. We also found that the combination
of the alternativeness and the effectiveness improved the per-
formance for the English test collection, whereas we could not find
this trend for the Japanese test collection.

As we discussed in Section 7, we have several limitations that
affect the performance of our method. One possible direction
would be improving the step for extracting candidate actions so
that we can obtain more relevant alternative actions. Another in-
teresting direction would be designing a new search interaction
so that a search system can encourage a searcher to carefully com-
pare the solutions suggested by the system and the one he/she
initially comes up with.
