1. Introduction

Large bowel volvulus is an uncommon cause of bowel obstruction in the industrialized world (1). However, it is four times more common in the Middle East than in Western countries (2). It constitutes the third leading cause of large bowel obstruction in Western countries after carcinoma and diverticulitis (3-5). India, Iran, and Russia have one of the higher incidences of sigmoid volvulus (6). Sigmoid volvulus occurs when the sigmoid colon twists axially around a narrow base of mesentery, leading to a close loop of bowel that is at risk of strangulation, ischemia, gangrene, and perforation (7,8).

Sigmoid volvulus is the most common cause of strangulation of the colon (4). It constitutes less than 10% of bowel obstructions in industrialized countries, compared with a rate as high as 25% in the developing regions of the world (9). Sigmoid volvulus, which often develops during the 7th and 8th decades of life, has been reported in young people as well (10) Oren et al. (11) found that the mean age of its incidence was 58 years. Liang et al. (12) corroborated that finding, and Liang et al. noted the highest prevalence of sigmoid volvulus in the 7th decade of life. Slidell et al. (13) reported three teenagers ages 17-19 with sigmoid volvulus. A 19-year-old male with the same signs and symptoms was encountered by Salinas et al. (7). Reported here are four cases of young male patients with sigmoid volvulus. All of the patients were diagnosed radiologically prior to surgical intervention. Two of the patients initially underwent an endoscopic procedure that succeeded in one and that failed in the other. Three of the patients underwent a laparotomy.

2. Case Report

2.1. Case 1

A 25-year-old Indian laborer presented to the Emergency Department with abdominal pain and absolute constipation for three days. The man occasionally vomited as well. The pain was colicky in nature. The man had no past medical history. He was afebrile with a distended abdomen and mild generalized tenderness. Bowel sounds were exaggerated. A rectal digital examination revealed an empty rectum. Abdominal
Roentgenography revealed a classic sign of sigmoid volvulus (coffee-bean sign) (3) (Figure 1). The man's WBC count was 18,000/mm$^3$ (4-11 mm$^3$) with a neutrophil percentage 80%. Serum electrolytes were: sodium 130 mmol/L (134-145 mmol/L), potassium 3.0 mmol/L (3.5 mmol/L), urea 5.5 mmol/L (2.9-9.3 mmol/L), and creatinine 110 micromol/L (80-115 micromol/L). Detorsion was attempted endoscopically but unsuccessful. A laparotomy was performed, revealing sigmoid volvulus.

2.2. Case 2

A 25-year-old male of Arab origin presented to the Emergency Department with colicky abdominal pain. The man had no past medical history. He vomited twice during the last couple of hours he was seen. The man had not moved his bowels for one week. His abdomen was moderately distended and globally tender. Bowel sounds were audible. A digital rectal examination revealed that the rectum was empty. The man had previously experienced three episodes of abdominal pain. Those episodes were of lesser severity and responded to analgesics. Analgesics failed to relieve the man's pain, so he sought medical attention.

2.3. Case 3

A 25-year-old male from the Indian sub-continent presented to the Emergency Department after two days of central abdominal pain along with nausea and obstipation. Two years ago, the man suffered the same problem, but it was fortunately relieved by oral analgesics. When he was seen by the Emergency Department, he was afebrile. An abdominal examination revealed a distension with tympanic percussion. Bowel sounds were present. Plain abdominal radiography revealed the coffee-bean sign indicative of sigmoid volvulus (3). Colonoscopy was attempted but was unsuccessful. A laparotomy was ultimately performed.

2.4. Case 4

A 35-year-old male from the Indian sub-continent was seen by the Emergency Department after multiple episodes of vomiting (yellow-colored) along with generalized abdominal pain lasting three days. The man had no past medical history. Clinically, he was sickly looking. His WBC count was 20,000/mm$^3$ with a neutrophil percentage of 84%. Serum electrolytes were: sodium 128 mmol/L, potassium 2.8 mmol/L, urea 10.5 mmol/L, and creatinine 115 micromol/L. His abdomen was distended with tympanic percussion. Bowel sounds were hyperactive. Initial plain abdominal radiography suggested sigmoid volvulus. A plain abdominal CT scan revealed the same features (Figure 2 and Figure 3). Colonoscopy revealed an obstruction 45 cm from the anal verge.

3. Discussion

Large bowel volvulus is more prevalent in the developing world, where it constitutes nearly 50% of all bowel obstructions as compared to only 5% in the developed world. In the Middle East alone, sigmoid volvulus is four times as common as it is in the Western world (1,2). There are a few contributing factors that are assumed to lead to large bowel volvulus in the Gulf region. The first is the dietary habits of the local population. People consume more junk food, less fiber (vegetables and fruits), and even less water. In addition, hot and humid weather leads to greater water loss from the body. Above all, a sedentary lifestyle is a leading factor for the development of sigmoid volvulus. Sigmoid Volvulus is more common in older patients, and especially those with a psychiatric co-morbidity (14,15). Sigmoid volvulus is also seen in patients suffering from Parkinson's disease, Alzheimer's disease, pseudobulbar palsy, and chronic schizophrenia (3). Oren et al. (11) reported a large series of 827 patients with a mean age of 57.9 years. Tiah et al. (16) studied 28 patients with an average age of 74 years and Liang et al. (12) studied 14 patients with an average age of 68.4 ± 12.2 years. In a study of 32 patients by Heis et al. (17), only two were under the age of 30; out of 30 cases of acute sigmoid volvulus, Sule et al. (18) found that 4 patients...
Hinshaw and Carter (20). Acute fulminating volvulus, caused by complete obstruction, clinically presents as sudden onset of central abdominal pain accompanied by emesis and constipation. Gangrene and perforation are common early complications of this type of volvulus. With subacute progressive volvulus, patients have only a partial obstruction and more insidious onset. Older patients frequently have the subacute form (21). The patients encountered by Heis et al. (17) presented with abdominal pain (96%), distension (84%), vomiting (72%), and constipation (63%). Kuzu et al. (22) noted abdominal distension in 89% of patients and vomiting in 64%. All of the current patients had abdominal pain, 75% vomited, and one only had nausea. Fifty percent of the current patients had constipation and 50% had were between the ages of 20-30 years. Slidell et al. (13) reported three teenagers with sigmoid volvulus. Salinas et al. (7) encountered a 19-year-old male with the same condition. In a study of 28 patients with acute sigmoid volvulus by Lou et al. (19), 19 were male and 9 were female with a mean age of 63.1 ± 22.9 years. All of the current patients were male. Three were 25 years old and one was 35 years old, representing a mean age of 27.5 years. All of the current patients were otherwise healthy with no noticeable medical illness (Table 1). Three of the current patients (75%) presented after 2-3 days while one was brought to the Emergency Department within a few hours of the onset of abdominal pain and vomiting.

Classically, sigmoid volvulus can be divided into two subtypes on clinical grounds, as described by
obstipation. All were afebrile.

Plain abdominal X-rays are a rapid and useful diagnostic tool (4,23). The classic coffee-bean sign on plain abdominal radiographs was found in 68.7% of patients encountered by Heis et al. (17) and in 68.5% of patients encountered by Khanna et al. (24). Javors et al. (25) found that sigmoid volvulus was diagnosed with X-rays in 87% of patients while Welch and Anderson (14) found that it was similarly diagnosed in 83% of patients. Tiah et al. (16) reported that sigmoid volvulus was diagnosed with plain abdominal radiography alone in 34.6% of cases. In suspected cases, a barium enema is recommended both as a diagnostic and therapeutic tool (26). CT provides the additional advantage of excluding other causes of intestinal obstruction in uncertain cases and also facilitating diagnosis of complications, such as a perforation (27). Early diagnosis can prevent ischemia or perforation (25) particularly in younger patients, in whom the chances of a misdiagnosis or a delayed diagnosis are higher (13).

A redundant segment of colon with a short mesentry and close proximity to the point of fixation to the segment are predisposing factors for the development of volvulus (2). Torsion of the sigmoid colon occurs along its mesenteric axis and axial torsion occurs around the axis of the bowel, leading to volvulus (28). The ileo-sigmoid knot is a rare but serious abdominal emergency in which the ileum and sigmoid entangle each other to form a knot; this can lead to vascular compromise and gangrene of both the ileum and sigmoid colon (21). Venous congestion compromises the colonic blood supply, which occasionally alleviates venous infarction and gangrene. Although less common, involvement of the arterial blood supply can expedite colonic ischemia.

The treatment of sigmoid volvulus remains controversial. It depends on the procedure selected in light of the clinical status of the patient, the location of the problem, the suspected existence or identification of peritonitis, bowel viability and, last but not least, the expertise of the surgical team (21). Surgeons generally have two surgical options. First, a single-stage procedure in which, initially, endoscopic derotation is followed by semi-elective sigmoidectomy and primary anastomosis (29). The second option is available when decompression fails and there are signs of colonic gangrene. This surgery is in two stages. In the first, a sigmoid resection and Hartman’s procedure or a double-barreled colostomy is performed in order to avoid a high rate mortality with primary anastomosis in that situation. In the second stage 6-8 weeks later, Hartman’s procedure is reversed or the colostomy is closed (30,31).

Presented here are unconventional cases of four young patients with a median age of 27.5 years. All of those patients had cramping abdominal pain, usually of several days’ duration. One of the patients experienced pain a few hours prior. Common symptoms among the patients were absolute constipation for a couple of days with occasional vomiting. The diagnostic tool Used was simple abdominal radiography. Three patients underwent Hartman’s procedure and one was managed with sigmoidoscopic decompression and semi-elective single-stage sigmoid resection with primary anastomosis.

4. Conclusion

Acute sigmoid volvulus is a common differential diagnosis in older patients who are bed-bound or who have a psychiatric co-morbidity. This condition should also be included in the differential diagnosis of young patients with colicky abdominal pain and absolute constipation. The chances of a misdiagnosis or a delayed diagnosis are greater when the symptoms are mild and recurrent. Plain abdominal radiography is a simple, inexpensive, and widely available diagnostic tool that should be used to screen for this rare but serious condition.
