Abstract

This study evaluates the flexural performance of precast concrete beams using ground granulated blast-furnace slag. A total of four specimens with various replacement ratios of ground granulated blast-furnace slag are cast and tested in flexure. The specimens under four-point loading had a shear span-to-depth ratio of 4 and a rectangular section with a width of 200 mm and an effective depth of 300 mm. It can be shown from experimental results that the specimens with ground granulated blast-furnace slag had a similar flexural performance to the specimen with natural aggregates, regardless of the replacement ratios of ground granulated blast-furnace slag.

Keywords: ground granulated blast-furnace slag; precast concrete beams; flexure; ductility

1. Introduction

Steel slag is divided into blast-furnace slag and steel-making slag based on its manufacturing process. Blast-furnace slag is generated from the high-temperature melting of raw materials, such as iron ore, coke, and limestone, in a blast furnace for making pig iron (Manso et al. 2004). Steel-making slag is divided into converter slag and electric-arc-furnace slag, which are industrial by-products generated from a converter or an electric-arc furnace with iron ore or scrap metal, respectively, being the main raw materials. The chemical composition of slag as an industrial by-product is similar to that of construction materials. The recycling of slag has a great advantage in terms of environmentally friendly use (Kim et al. 2012a, 2012b; Lee et al. 2011; Becknell and Hale 2011), such as recycled aggregates obtained from waste concrete (Kim et al. 2013; Kang et al. 2014).

Blast-furnace slag is composed of SiO₂, Al₂O₃, CaO, and MgO, which is very similar to Portland cement, and so is the hydration reaction of blast-furnace slag. However, ground granulated blast-furnace slag has a so-called "latent hydraulic property" which cannot react without CH as a catalyst generated in the hydration reaction of cement (Mehta and Monteiro 2006). Therefore, if cement is replaced with a large volume of ground granulated blast-furnace slag, the strength of the concrete decreases owing to the delay of the hydration reaction (Mehta and Monteiro 2006).

A lot of studies have reported that the long-term strength and durability of concrete with ground granulated blast-furnace slag is superior to that of concrete with Portland cement only. The higher the replacement ratio of the ground granulated blast-furnace slag is, the lower the required unit-water content for the same slump is. Therefore, ground granulated blast-furnace slag is good for making high-flowing, high-strength, and high-durability concrete. If blast-furnace slag is used as an alternative cement material, the production cost of concrete can be reduced, as well as the CO₂ emissions from Portland cement production.

Recently, the use of precast concrete structures, which can minimize fieldwork, ensure construction quality, and reduce construction time, is increasing. Because precast concrete members can be treated by steam curing in a factory during the early stage of concrete curing, it can improve the early-age strength of concrete and ensure its quality. Such advantages could resolve the problem of low early-age strength when a large amount of ground granulated blast-furnace slag is added to concrete so that, in terms of slag recycling, it is greatly beneficial. Despite the benefits of its use, few studies have been carried out on the use of ground granulated blast-furnace slag.
in precast concrete. This study evaluated the flexural performance of precast concrete beams in order to promote the active use of ground granulated blast-furnace slag.

2. Experimental Program

2.1 Materials

In this study, the design strength of concrete was designed to 45 MPa, as listed in Table 1. The compression test of the concrete cylinder was carried out at the time of the parent specimen test. The average compressive strengths of concrete are indicated in Table 2. and the compressive stress versus strain relationships of concrete are presented in Fig.1.(a).

Three types of reinforcement, D10 (71.3 mm²), D13 (126.7 mm²), and D22 (387.1 mm²), were used in this test. D13 for compression reinforcement had yield strength of 471.0 MPa and D22 for tension reinforcement had yield strength of 448.7 MPa. The D10 steel bar with yield strength of 496.6 MPa was used for shear reinforcement. The stress versus strain relationships of the reinforcement are shown in Fig.1.(b).

2.2 Test Varieties

A total of five specimens were cast and tested in this study to evaluate the flexural performance of precast concrete beams with ground granulated blast-furnace slag, as shown in Table 2. Each simply supported specimen was designed to have a clear span of 2,900 mm and a cross section of 200×350 mm, as seen in Fig.2. The shear span-to-depth ratio and the tension reinforcement ratio of the specimens were designed to 4 and 1.94%, respectively, to induce flexural failure of the specimens. The shear reinforcement spaced at 100 mm was designed to prevent shear failure prior to flexural failure.

Strain gauges were attached to the tension, compression, and shear reinforcement to measure the deformation of the reinforcement, as seen in Fig.2.

Furthermore, strain gauges were installed at the mid-span of the specimen to track the neutral axis and curvature, as shown in Fig.2.
2.3 Test Setup
As seen in Fig.3, a four-point loading system was applied to the specimens using a universal testing machine (UTM) with a load capacity of 1,000 kN. The applied load was removed when the post-peak load dropped to under approximately 85% of the maximum load. At the mid-span of the specimens, two linear variable differential transducers (LVDTs) were installed on the bottom of the specimens to measure the deflection of the specimens.

3. Test Results
3.1 Load versus Deflection Relationships
The load-deflection relationships measured from the experiment are shown in Fig.4. The deflection was the average value obtained from the LVDTs installed at the bottom of the specimens, as seen in Fig.3. It can be found from Fig.4 that all specimens exhibited similar ductile flexural behavior regardless of the replacement ratio of ground granulated blast-furnace slag.

The initial flexural crack occurred at 24.3~32.3 kN, whereas the tension reinforcement reached the yield strain at 222.1~241.5 kN. The maximum strength was found to be 273.2~280.9 kN, but the moment capacity declined due to the crushing of concrete in the compression zone, as seen in Fig.4.

3.2 Crack Patterns
The crack patterns of tested specimens according to the compressive strength of concrete and the replacement ratio of ground granulated blast-furnace slag are presented in Fig.5. The specimens had similar crack patterns even with varying values for the replacement ratio of the blast-furnace slag.

Flexural cracks formed at the mid-span of specimens during the initial loading, and expanded into both ends of the specimens as the load increased. After the tension reinforcement reached the yield strain, the cracks rapidly developed toward the loading points with an increase in crack width. Finally, the specimens failed in flexure with concrete crushing in the compression zone between loading points.

4. Discussion of Test Results
4.1 Flexural Strength
The yield moment, \( M_y \), can be obtained using equilibrium and Hook’s law as follows:

\[
M_y = C_c \left( d - \frac{1}{3}kd \right) + C_t \left( d - d' \right) = T \left( d - \frac{1}{3}kd \right) \tag{1}
\]

where \( C_c \) is the concrete compression force, \( C_t \) is the force in the compression reinforcement, \( T \) is the tension force, \( d \) is the effective depth, \( d' \) is the distance from extreme compression fiber to the centroid of compression tension reinforcement, and \( kd \) is the distance from the neutral axis to the extreme compression fiber at yielding of tension reinforcement.
The ultimate moment, \( M_u \), can be expressed using the equivalent stress block as follows:

\[
M_u = \alpha f' \beta \left( \frac{d - \beta c}{2} \right) + A_s f_y \left( d - d' \right)
\]

where \( \alpha \) is the coefficient of the compression stress block, \( f'_c \) is the compressive strength of the concrete, \( \beta \) is the ratio of the depth of rectangular stress block, taken as \( a/c \), \( a \) and \( c \) is the distance from extreme compression fiber to neutral axis at first yield and ultimate, respectively, \( b \) is the beam width, \( A_s \) is the area of compression reinforcement, and \( f_y \) is the stress of compression reinforcement. This study uses the coefficients of the compression stress block proposed by ACI 318-11 (ACI 2011).

Table 3. presents a comparison of the experimental and analytical results for yield moment calculated by using Eq. (1). As shown in Table 3., the analytical results for the yield moment accurately estimated the experimental results with a mean of 0.98. It can be seen from Table 3. that the experimental results on ultimate moment, corresponding to maximum moment in this study, for each specimen exceed the analytical results proposed by ACI 318-11 by about 20%. This means that the ground granulated blast-furnace slag used in the precast concrete can harden with sufficient flexural strength even if up to 70% of ground granulated blast-furnace slag is replaced. However, further research is needed to find the allowable maximum replacement ratio of ground granulated blast-furnace slag in precast concrete.

### 4.2 Moment versus Curvature Relationships

Measured moment-curvature relations of each specimen are presented in Table 3. and Fig.6. The real curvature of each specimen was obtained by using the strain gauges attached to tension and compression reinforcement at the mid-span of specimens and the Bernoulli principle. In this study, ultimate means the state at reaching the flexural strength of the specimen.

The curvature at first yield of tension reinforcement can be calculated as follows:

\[
\phi_y = \frac{f_y}{d(1-k)} = \frac{\varepsilon_y}{d(1-k)}
\]

where \( f_y \) is the yield strength of tension reinforcement, \( E_s \) is the elastic modulus of tension reinforcement, and \( \varepsilon_y \) is the yield strain of tension reinforcement.

The ultimate curvature, \( \phi_u \), was calculated using the following equation:

\[
\phi_u = \frac{\varepsilon_c}{c} = \frac{\varepsilon_c \beta I}{a}
\]

where \( \varepsilon_c \) is the strain of the concrete at extreme compression fiber.

Fig.6. indicates that analytical results for the moment-curvature relationship coincide fairly accurately with experimental results regardless of the replacement ratio of ground granulated blast-furnace slag. The experimental results of the yield curvature were obtained from the strain at the first yield of tensile reinforcement. As shown in Table 3., the experimental and calculated results for the yield curvature show good agreement with a mean of 0.99.

The experimental results of the ultimate curvature were obtained from the curvature corresponding to ultimate moment in this study. As indicated in Table 3., the specimen with ground granulated blast-furnace slag showed superior deformation performance that is approximately 3 times better than the analytical results.

### 4.3 Effective Moment of Inertia

ACI 318-11 (ACI 2011) recommends the following effective moment of inertia, \( I_e \), proposed by Branson (1965) to calculate the deflection of RC members under service load.

\[
I_e = \left( \frac{\alpha M_s}{M_u} \right) I_e + \left[ 1 - \left( \frac{\alpha M_s}{M_u} \right)^3 \right] I_{cr}
\]
where $M_c$ is the cracking moment, $f_c$ is the modulus of rupture, taken as $0.65f'_c$, $I_c$ is the moment of inertia of the gross concrete section neglecting reinforcement, $y_c$ is the distance from the centroid axis of the cross section to the extreme fiber in tension, $M_s$ is the maximum moment in a member at the stage deflection is computed, and $I_{cr}$ is the moment of inertia of the cracked section transformed to the concrete.

When the bending moment, $M_s$, is applied to a simply supported beam under four-point loading, the theoretical deflection of the beam can be calculated as follows based on the theory of elasticity:

$$\Delta_s = \frac{M_s a}{24E I_c} \left(3L^2 - 4a^2\right)$$

(7)

where $a$ is the shear span, $L$ is the clear span measured center to center of the supports, and $E_i$ is the elastic modulus of the concrete.

The moment of inertia of the specimen measured from the experiment at loading stage $M_s$ can be derived as follows:

$$I_{exp} = \frac{M_s a}{24E_i \Delta_{exp}} \left(3L^2 - 4a^2\right)$$

(8)

where $\Delta_{exp}$ is the deflection measured by LVDTs installed under the mid-span of the specimen.

The analytical and experimental results of the effective moment of inertia of the specimens under service load are given in Fig.7. The analytical results of the effective moment of inertia calculated by using ACI 318-11 predicted well the experimental results, irrespective of the replacement ratio of the ground granulated blast-furnace slag. Therefore, the existing flexural theory can be used for predicting the flexural deformation of the precast concrete beams with ground granulated blast-furnace slag.

4.4 Ductility

Ductility is the ability of a section, structural member, or structural system to maintain inelastic deformation prior to failure without substantial loss in resistance (Naaman et al. 1986). The ductility of structural members is usually represented as the ratio of the deformation at ultimate state to the deformation at first yield of tension reinforcement (Park and Paulay 1975). In this study, the ductility of specimens was evaluated using the following displacement ductility index.

$$\mu_D = \frac{\Delta_{cr}}{\Delta_y}$$

(9)

where $\Delta_{cr}$ is the displacement corresponding to ultimate moment and $\Delta_y$ is the displacement at first yield of tension reinforcement.

The displacement ductility index of tested specimens is given in Table 3. As shown in Table 3., the ductility index of Specimen BG0 was 2.27, whereas those of Specimens BG30, BG50, and BG70 were 2.69, 2.88, and 2.35. That is, the ductility capacity of specimens with ground granulated blast-furnace slag is superior for use as structural members and is sufficiently safe.

4.5 Serviceability

The number of cracks and crack widths according to applied moment are shown in Fig.8. and Fig.9., respectively. For all specimens, the number of cracks and crack widths increased with greater load. In Fig.8., which shows the load-number of crack relationships for each specimen, all specimens exhibited similar load-crack relationships except for Specimen BG70 with 70% replacement of ground granulated blast-furnace slag. Specimen BG70 had relatively fewer cracks in service load, but formed 23 cracks at ultimate load, similar to the number of cracks in other specimens.

As shown in Fig.9., all specimens had a crack width smaller than 0.3 mm in the service load, thus satisfying the crack width limitation at service loads recommended by current code provisions (KCI 2012).
In addition, all specimens had similar crack widths in the service load state regardless of the replacement ratio of ground granulated blast-furnace slag.

5. Conclusions
This study evaluates the flexural performance of precast concrete beams with ground granulated blast-furnace slag. Based on the experimental results, the following conclusions were drawn:

1) In this experiment, precast concrete specimens with ground granulated blast-furnace slag showed similar flexural strength and higher ductility capacity compared to cement-only specimens.

2) The crack patterns and the change in effective moment of inertia for all specimens were similar, regardless of the replacement ratio of ground granulated blast-furnace slag.

3) Analytical results using existing flexural theory predicted well the yield and ultimate moment of specimens with ground granulated blast-furnace slag. In particular, the experimental results for ultimate moment of specimens with blast-furnace slag were approximately 1.2 times higher than existing analytical results.

4) This study evaluated the serviceability of precast concrete beams with ground granulated blast-furnace slag, and found that crack widths were smaller than 0.3 mm limited by current code provisions.

Based on the experimental results, precast concrete beam specimens with ground granulated blast-furnace slag showed superior flexural performance. However further research is needed to find the allowable maximum replacement ratio of ground granulated blast-furnace slag in precast concrete members.

Notations
\( a \) = shear span  
\( A_c \) = area of compression reinforcement  
\( b \) = beam width  
\( C_c \) = concrete compression force  
\( C_r \) = force in compression reinforcement  
\( d \) = effective depth of beam  
\( d_e \) = distance from extreme compression fiber to the centroid of compression tension reinforcement  
\( E_c \) = elastic modulus of concrete  
\( E_s \) = elastic modulus of reinforcement  
\( f_{cr} \) = modulus of rupture  
\( f_y \) = yield strength of reinforcement  
\( f'_{c} \) = compressive strength of concrete  
\( f'_{s} \) = stress of compression reinforcement  
\( I_{cr} \) = moment of inertia of cracked section transformed to the concrete  
\( I_e \) = effective moment of inertia  
\( I_g \) = moment of inertia of the gross concrete section neglecting reinforcement  
\( k_d \) = distance from the neutral axis to the extreme compression fiber at yielding of tension reinforcing bars  
\( L \) = clear span measured center to center of the supports  
\( M_a \) = maximum moment in member at stage deflection  
\( M_c \) = cracking moment  
\( M_y \) = yield moment  
\( M_u \) = ultimate moment  
\( T \) = tension force  
\( y_t \) = distance from the centroid axis of the cross section to the extreme fiber in tension  
\( \alpha \) = coefficient of the compression stress block  
\( \beta_t \) = ratio of the depth of rectangular stress block  
\( \varepsilon_c \) = strain of the concrete at extreme compression fiber  
\( \varepsilon_y \) = yield strain of tension reinforcement  
\( \phi_r \) = curvature at first yield of tension reinforcement  
\( \phi_u \) = ultimate curvature  
\( \Delta_{exp} \) = deflection measured LVDTs installed under the mid-span of the specimen  
\( \Delta_c \) = displacement at first yield of tension reinforcement  
\( \Delta_e \) = displacement corresponding to ultimate moment
