REVIEW

Recent Progress of Strawberry Year-round Production Technology in Japan

Field Crop and Horticulture Division, NARO Tohoku Agriculture Research Center, National Agriculture and Food Research Organization (NARO) (Morioka, Iwate 020-0123, Japan)

Abstract

In Japan, more than 90% of strawberries are produced by forcing culture, which involves inducing flowering in autumn by several artificial methods (e.g. chilling, short-day), growing plants under a heated greenhouse to avoid the induction of dormancy and dwarfing, and keeping them in a semi-dormant state to allow continued harvesting. Although the normal harvest period is from late November to June, progress in technological research and the development of forcing has contributed to such long-term harvests. In forcing culture, it is important to understand the dormancy status of the strawberry plants, since controlling dormancy is key to realizing long-term successive harvests between winter and early summer. However, the last two decades have seen increasing demand for a year-round supply of strawberries for confectioners. Recent progress in the research and development of strawberry year-round production technology is reviewed with special reference to the activities of a summer-autumn production research team in the Tohoku region.

Discipline: Horticulture

Additional key words: dormancy, everbearing, flower initiation, forcing culture, high temperature

Introduction

Wild species from North and South America are the origin of the cultivated strawberry, a winter-dormant plant for which relatively cool climates are standard. Low temperatures or short-day photoperiods in autumn induce flower bud initiation and the start of dormancy, which is later broken by sufficient chilling. The subsequent high temperatures and long-day photoperiods in spring promote vegetative growth, leaf elongation, runner development, and blooming. Based on this life cycle, strawberries are usually harvested from May to June in open fields. Over several decades, the production season has been extended to mid-November, and continuing into May. These changes represent remarkable progress in terms of developing a successive production system, strawberry forcing cultivation technology, and breeding new varieties. This progress is the result of research conducted at Japanese research institutes and universities^{13, 24}. However, as a result, the supply of strawberries has been focused on winter and spring seasons in Japan. From July to October, when

strawberries are scarce, imported fruit from California meet demand. However, the increasing demand for summer-autumn strawberries from confectioners has spurred research into summer-autumn production.

The following is a review of the research achievements describing the current state of year-round strawberry production technology, with special reference to the results of the research project around the Tohoku region.

Establishment of forcing culture

In Japan, more than 90 percent of strawberries are produced by forcing and semi-forcing culture. The forcing culture originated with a “*Ishigaki ichigo*” in Shizuoka, whereupon many technical problems related to breeding, growth, and development were subsequently solved. The “Hoko wase” cultivar was used to pioneer long-term forcing cultivation with supplemental lighting and gibberellin application; led by Fujimoto (1972) in Nara Prefecture². Fujimoto’s research enabled long-term, out-of-season production from December to June. The stable supply of virus-free plants from the regional foundation stock farms

also contributed significantly to the establishment of forcing culture²¹.

Conversely, the temperature differences and harsher winters in northern locales, such as Hokkaido and Tohoku, meant other cultivation systems were necessary, one of which, developed by Takai and Seyama (1978), is a dormancy-extended semi-forcing culture²². Here, chilling is controlled so that the dormancy is not completely broken and successive flowering and vegetative vigor continues from April to July.

In both systems, the importance of controlling the dormant status for successive flowering and shoot growth should be emphasized. The dormancy of strawberry plants is induced by a short-day photoperiod and low temperature and released by sufficient chilling. In spring, dormancy-broken plants produce a long petiole and large leaf blades and runner stolons, and cease to initiate flower bud, even if exposed to a suitable temperature and photoperiod for flower budding for several months (Fig. 1). Therefore, in the Japanese forcing culture, the winter temperature needs

to be regulated so that the plants are not exposed to dormancy-inducing low temperature, normally below 5°C¹⁴. Furthermore, the plants need to be kept in a non-dormant or semi-dormant state, because sufficiently chilled plants break their dormancy and cease to initiate flower bud^{20, 35}.

Subsequently the interest of growers and researchers turned toward progress in harvesting time, as the varieties used for forcing culture were those with fewer chilling requirements. In earlier research, nitrogen was assumed to be heavily involved in the flower bud initiation process². Consequently, waiting beds in nursery plant production, which required root pruning, rapidly gave way to the use of polyethylene pots or plugging. Nursery plant production by pots and plugs was effective, not only for early harvesting in November but also for protecting plants from anthracnose and Fusarium wilt, but required more labor. In the 1980s, new techniques for flower bud induction, such as short-day/low-temperature treatment and dark/low-temperature treatment (10-15°C), mainly for ‘Nyoho’ and ‘Toyonoka’, respectively, were established

Fig. 1. Effect of chilling on vegetative vigor, runner production and flowering

^z Number of hours exposed to temperature below 5 °C

‘Sachinoka’ plants were transferred to a warm greenhouse (min. 18 °C/12 hr photoperiod) from outside at 20- or 30-day intervals. The inflorescences were removed after the blooming of the first flower.

and widely adopted in areas with forcing culture. Simultaneously, limiting the nitrogen supply for flower bud induction also became an essential cultural technique^{6, 25, 29} and enabled such induction at any time. However, actual year-round production was not practiced because the excessive progress of flower initiation inhibited successive flowering, and fruit quality could not be maintained in the high summer and autumn temperatures. In summary, the main factors affecting year-round production are the maintenance of successive flowering and fruit quality at high temperatures.

Current research into summer-autumn production

As reported above, the harvest season for forcing culture is currently November to June. From July to October, when strawberries are scarce, imported fruit from California meets demand. However, confectioners have increased their demand for summer-autumn strawberries, which has spurred research into summer-autumn production.

Until the 1980s, many researchers sought a solution to the difficult problem of fruit production in summer and autumn with June-bearing varieties, due to the lack of high-quality ever-bearing varieties at that time.

1. Use of June-bearing varieties

Summer-autumn production using cold-stored plants was temporarily widespread in Japan in the 1960s and 1970s. Since cold-stored plants are placed in chilled storage at -1°C, they do not initiate new flower buds and consequently have a low yield. Subsequently, however, this production gradually disappeared in favor of forcing culture as the mainstream and increased imports from the United States.

However, cold-stored plants are used globally, with successive cropping of 'Elsanta' performed in the Netherlands and Belgium and spring transplanting in California. Cold-stored plants have also recently been tested for successive cropping or varietal performance in Japan^{34, 36}.

Furthermore, summer-autumn production achieved with short days was also investigated in the colder parts of Japan in the 1960s. Recently, project-team research conducted in the Tohoku region produced interesting results from summer-autumn production, based on which small growing districts are now developing³¹. A new method of short-day treatment for daughter plant production using runner-connected mother plants was also developed²⁸. However, in cold areas, summer-autumn production achieved with short-day treatments presents its own problems, such as the interruption of successive flowering. When growers want to continue forcing culture by maintaining appropriate temperatures with the same plants

used for summer-autumn culture in winter, they will have several months of blank harvest. Excessive progress of flower bud initiation usually inhibits the axillary flower bud initiation in this cropping system because the thermal and photoperiodical conditions at the time of transplanting in summer are unsuitable for flower bud initiation. It is therefore preferable to cease applying the maintaining temperature in cold areas following the harvest of forced primary inflorescence, whereupon plants are forced to be dormant for a while. Subsequently, in early spring, plants start to regrow and bloom. With this method, plants are overexposed to low temperatures to break their dormancy and thus temporarily stop responding to any flower bud induction stimulus. In other words, successive flowering temporarily stops. This phenomenon is also known as a "post-chilling physiological condition" and is considered to impair forcing culture in cold northern areas. Recently, a study quantifying the period for which strawberry plants do not respond to flowering stimulus after sufficient chilling was conducted³⁵. Although maintaining temperatures in winter is economically possible in cold districts, it is very difficult to maintain successive flowering after the chilling requirement is satisfied and further studies on dormancy and the flowering process are required. In future, it would be beneficial to develop an improved forcing culture for cold areas where the cost of maintaining warmer temperatures is expensive.

In areas with a Mediterranean climate, such as California, the flowering habits of some June-bearing varieties sometimes change to everbearing varieties³³, which is known as the "California effect". In Japan, the seasons are more pronounced than in California. However, if the exposure to chilling were reduced and dormancy maintained over winter, it would be possible to create an artificial "California effect" on the Pacific seaboard of northern Tohoku and Hokkaido¹². The recently released early-flowering varieties, such as 'Saga-honoka,' will help make this possible. In the near future, new techniques for forcing culture that are more suited to cold districts should be developed.

2. Use of everbearing varieties

In recent decades, everbearing varieties have been actively and intensively bred and released by government institutes and private companies²³, although limited information exists on the growth and flowering habits of everbearers. Everbearing varieties, including day-neutral ones, are considered insensitive to photoperiod in flower bud initiation, but some were recently determined as long-day plants under a high-temperature regime^{15, 16}. For example, most everbearers develop fewer runner plants than Junebearers. In addition, everbearers sometimes develop

excessive branch crowns, inflorescences, and flowers, meaning more management and labor is required for de-budding, pruning, and thinning. Some recent noteworthy work includes studies on the photoperiodic response of flowering under high temperature regimes^{15, 16, 18}, flower induction by long-day treatment⁹, the high temperature effects on flowering and fertilization^{3, 4}, the involvement of chilling and runner production^{7, 8}, seasonal changes in fruit sugar content⁵, the analysis of root structure³⁰, and the application to forcing culture¹⁰. Despite the shortage of information on flowering physiology, there are many active breeding programs involving new everbearing varieties in public and private institutions.

It is also very difficult for both everbearers and Junebearers alike to overcome the effects of high summer temperatures, which affect the stability of flowering, fruit quality, and shelf life. However, the production area has spread to over 80 ha in Japan and is still increasing.

Improvement of cultural conditions, especially high-temperature summer regimes

As reported above, it is crucial to improve cultural conditions, especially high-temperature summer regimes, not only in Junebearers but also in everbearers. Several studies have been performed on the high-temperature effects on fruit development and fruit quality¹⁹, and it is obvious that high temperatures inhibit fruit growth and development and impair quality. Many technological approaches for coping with high temperatures within a greenhouse or high tunnels have been developed, several of which were presented at the 2007 spring JSHS symposium²⁷. For strawberries, there have been many trials to improve the temperature conditions around strawberry plants in summer, including localized cooling along the crown by cold water flowing in an aluminum tube¹, root zone aeration¹¹, and substrate cooling by vaporization from a porous sheet^{17, 32}.

Since nursery plants are not suited to high summer temperatures, plants were taken to higher elevations to induce flower buds in forcing culture until the 1980s. Recently, the long-distance movement of nursery plants has been implemented between Hokkaido and areas used for forcing culture instead of higher elevations. Saving labor is also a key issue in Japanese strawberry culture. In Japan, the number of working hours spent on nursery plant production is generally 15 to 20% of the total working hours expended on forcing culture fruit production. Progress in the specialization of nurseries by such long-distance nurseries could reduce the labor of many Japanese strawberry farmers in nursery production and promote large-scale fruit production.

To promote the specialization of nursery plant production, other special values should be added to the nursery plant, e.g. low price and the presence of flower buds. Currently, a unique nursery system is being developed, in which short-day treatment in summer-autumn production is simultaneously applied to daughter plants connected to mother plants by runners at a nursery site. The development of the labor- and cost-saving mass production of nursery plants with flower buds is anticipated²⁸.
