We studied the effects of a widely-used sulfonylurea, gliclazide, on the oxidizability of low-density lipoprotein (LDL) and the development of experimental atherosclerosis in cholesterol-fed rabbits. Daily oral administration of gliclazide (20 mg/kg/day) tended to inhibit the aortic atherosclerosis induced by feeding a 1% cholesterol diet for 10 weeks, although it did not affect diet-induced hyperlipidemia. The administration of gliclazide tended to inhibit the increase of serum thiobarbituric acid-reacting substances (TBARS) by cholesterol feeding and to increase the lag time of the conjugated diene formation of LDL subjected to in vitro oxidation by copper ion, although without significance. The present study suggests that gliclazide may have antioxidative properties in vivo, and have further beneficial effects for the treatment of diabetes mellitus by inhibiting the oxidation of LDL. J Atheroscler Thromb, 2000; 7: 104-109.

Key words: Gliclazide, Low-density lipoprotein, Antioxidant, Atherosclerosis

Introduction

Coronary artery disease is the leading cause of death in diabetes mellitus, and diabetes confers a two- to four-fold relative risk of developing coronary artery disease (1). Even when adjusted for other risk factors such as hypertension and hyperlipidemia, diabetes remains an important cardiovascular risk factor. Diabetes causes a thrombogenic tendency in patients, with increased platelet reactivity, impaired fibrinolytic activity, and increased oxidative stress (2).

It has been shown that hyperglycemia causes the production of free radicals in several ways (3). This may contribute to the development of diabetic macrovascular complications through increased oxidation of low-density lipoprotein (LDL), which is thought to be a crucial step in the development of atherosclerosis (4, 5).

Gliclazide, a sulfonylurea in routine clinical use in many countries including Japan, has been shown to have free radical-scavenging activity in vitro and to be an effective inhibitor of in vitro LDL oxidation and more potent on a molar basis than vitamin C (6). This antioxidant property of gliclazide is not shared by other sulfonylureas such as glibenclamide, tolbutamide and glipizide.

The oxidative modification of LDL is considered to be an important step in the development of atherosclerosis. After initial oxidation of the polyunsaturated fatty acid component of LDL, peroxide products attack the lysine groups of apoprotein B, altering its receptor affinity and allowing uptake by the scavenger receptor on macrophages (4). Therefore, an agent that inhibits LDL oxidation may have the potential to prevent or retard the development of atherosclerosis.

In 1978, Marquie reported that the administration of gliclazide strongly inhibited the development of aortic and particularly coronary lesions induced by the atherogenic diet but did not inhibit the development of plasma lipid disturbances induced by the diet (7). However, he did not study the oxidative stress and did not discuss the antiatherogenic mechanisms of gliclazide.

In the present study, we studied the effects of gliclazide...
on LDL oxidizability and atherosclerosis induced by cholesterol feeding in rabbits.

Materials and Methods

Animals and study design
Sixteen male New Zealand White rabbits (Kitayama, Japan) were housed individually at 24 ± 1°C with a 12-hour light:dark cycle. They were allowed free access to water and commercial rabbit nonpurified diet for 10 days to enable them to adapt to the new environment. Then rabbits were divided into two groups with matched body weights and serum cholesterol and triglyceride concentrations. The control group (n = 8) was given a standard diet containing 1% cholesterol. The gliclazide group (n = 8) was given a standard diet containing 1% cholesterol and supplemented with gliclazide (20 mg/kg/day). Each rabbit was given 100 g of its respective diet daily in the morning for 10 weeks. One rabbit in the gliclazide group died of pneumonia during the study period and was excluded from the statistical analysis. Dietary consumption did not differ between the two groups of animals during the study period (data not shown). All the protocols for animal experiments were approved by the Laboratory Animal Care Advisory Committee of Nagoya University.

Blood sampling
Blood samples after overnight fasting for 16 hours were obtained from an ear artery at the beginning of the study, after 4 weeks, and at the end of the study period (10 weeks).

After 3 weeks of treatment, blood samples were taken from 3 rabbits in each group before, 1 hour, 3 hours, and 6 hours after receiving the diet in the morning and serum glucose was measured.

Serum was stored at -80°C until assay.

LDL isolation and oxidation
LDL was isolated by ultracentrifugation followed by in vitro copper-induced LDL oxidation (8, 9). In brief, after isolation, the LDL was dialyzed for 24 hours in the dark at 4°C against phosphate-buffered saline (PBS) containing 10 μmol/L EDTA. The LDL-containing sample was filtered through a 0.45-μm filter and diluted with dialysis buffer to a final concentration of 100 μg protein/mL. The oxidation was initiated by the addition of freshly prepared 10 μmol/L CuSO4 solution. The kinetics of the oxidation of LDL were determined by monitoring the change of the 234-nm diene absorption on a UV spectrophotometer (Shimadzu, Tokyo, Japan) at 37°C. The change of absorbance at 234 nm versus time was divided into three phases, i.e., a lag phase, a propagation phase, and a decomposition phase. Lag time was calculated as described elsewhere.

Extent of aortic atherosclerosis
At the end of the study period, rabbits were killed by administration of a bolus injection of sodium pentobarbital. Immediately thereafter, aortas were removed from the arch to the descending thoracic aorta. The aortas were cleaned of excess adventitial tissue, and rinsed with saline and opened longitudinally. After photographing, the aortas were fixed with formalin for histological analysis. The weight of the excised heart, kidneys, and liver was also measured. The area covered by atherosclerotic lesion was quantified with a planimetry system.

Other methods
Serum total cholesterol, HDL-cholesterol and triglycerides were determined by commercially available enzymatic assay kits. Serum glucose was determined enzymatically using a glucose autoanalyzer (YSI2300 Stat Plus, Yellow Springs Instrument, Yellow Springs, OH, USA). Protein was determined with a bicinchoninic acid protein assay kit (Pierce, Rockford, IL, USA), using bovine serum albumin as the standard. The extent of lipid peroxidation in serum was determined as 2-thiobarbituric acid (TBA) reacting substances (TBARS) as described previously (10). The concentration of gliclazide in serum and LDL was measured using the HPLC method as described previously (11).

Statistics
Results are expressed as mean ± S.D. unless otherwise stated. Statistical evaluation was performed using the paired Student's t test, with a p value of <0.05 considered to be significant.

Results
Food intake and growth
Dietary consumption did not differ between the two groups of animals during the study period (data not shown). Weight gain also did not differ between the two
groups (Fig. 1).

**Serum lipids and glucose**

Serum total cholesterol, HDL-cholesterol and triglyceride levels were similar between the two groups during the study period (Figs. 2A-C).

The concentration of TBARS in serum was determined as an indication of lipid peroxidation in vivo. Serum TBARS increased with cholesterol feeding, and was slightly, but not significantly lower in the gliclazide group than the control (p=0.13 at 10 weeks) (D).

The fasting serum glucose level was not different between the two groups (Fig. 3). After 3 weeks of treatment, blood samples were taken from the 3 rabbits of each group before, 1 hour, 3 hours and 6 hours after receiving the diet in the morning. Slight decreases of serum glucose were demonstrated 1 and 3 hours after feeding in the control group without significance. Slight but not significant decreases of serum glucose were demonstrated 1 to 6 hours after feeding in the gliclazide group.
Concentration of gliclazide

The concentration of gliclazide in the serum was measured using the HPLC method (Fig. 3). The concentration of gliclazide in serum increased up to 6 hours after receiving the gliclazide-containing diet in the morning. No gliclazide was detected in serum at the beginning of the experiment in the gliclazide group or in the control group during the study. Gliclazide was not detected in LDL even after receiving the gliclazide-containing diet (data not shown).

LDL oxidizability

The oxidizability of LDL was determined in vitro by continuously measuring the conjugated-diene production induced by incubation with copper. Supplementing the rabbit diet with gliclazide resulted in a 36.7% increase in lag time after 4 weeks of treatment although without significance (Fig. 4). Prolonged treatment did not lead to a further increase in lag time.

Aortic atherosclerosis

At the end of the study period, the rabbits were killed and their aortas were removed to quantify the extent of atherosclerotic lesion formation. Gliclazide treatment tended to result in a somewhat smaller area covered with atherosclerotic lesions compared with the control, although this was not statistically significant (Fig. 5).

Other organs

No difference in the weights of heart, liver and kidneys were observed between the gliclazide group and control group (data not shown).

Discussion

Gliclazide is a second generation sulfonylurea that is widely used in the treatment of type II diabetes mellitus and its hypoglycemic activity is well documented (2, 12). In addition to its metabolic effects, gliclazide has beneficial effects on the hemobiological abnormalities of type II diabetes. These effects are mediated by the azacyclocloctyl ring grafted on to its sulfonylurea core (2).

Numerous studies have demonstrated that gliclazide reduces platelet hyperadhesion and platelet hyperaggregability (2). The beneficial effects of the compound on thromboxane/prostacyclin balance have been recently confirmed in type II diabetic patients (13). Concerning fibrinolysis, gliclazide restores low plasminogen activity to normal in type II diabetic patients previously treated with first-generation sulfonylureas (14). Gliclazide increases the fibrinolytic potential by increasing endothelial cell tissue plasminogen activator and prekallikrein activity (15). More recent studies suggest that gliclazide may have effects on the fibrin network structure, rendering the fibrin more amenable to fibrinolysis (16). Diabetes was associated with significant impairment of acetylcholine-induced endothelium-dependent relaxation of the abdominal aorta which was not significant in diabetic rabbits treated with gliclazide in vivo (17). Aortas from diabetic rabbits studied in the presence of a nitric oxide synthase inhibitor, L-NAME showed an exaggerated contraction to acetylcholine which was prevented in rabbits treated with gliclazide.

Furthermore, gliclazide has been shown to have a potent free-radical-scavenging activity in vitro. Glica-
glipizide scavenges free radicals such as superoxide anion, hydroxyl radical, and nitric oxide in a dose-dependent manner (18, 19). The resistance to oxidation, expressed as the lag time between the addition of copper and commencement of oxidation, was significantly increased by the addition of glipizide in vitro (20). LDL isolated from diabetic subjects supplemented with glipizide had an increased lag time compared with untreated LDL, although other sulfonylureas including glibenclamide, glipizide, and tolbutamide had no effect on lag time. Incubation of human monocytes and bovine endothelial cells with increasing concentrations of glipizide (2.5 to 10 μg/ml) and native LDL induced a dose-dependent inhibition of cell-mediated LDL oxidation. In addition, exposure of endothelial cells to glipizide and native LDL induced a dose-dependent diminution of the oxidized LDL-induced monocyte adhesion to bovine endothelial cells (20).

Diabetic patients showed increased levels of circulating modified lipoproteins and enhanced oxidation of plasma LDL. Increased production of malondialdehyde, a marker of lipid peroxidation, has also been found in erythrocyte membranes of diabetic patients. Circulating levels of MDA are also higher in the plasma of diabetic patients compared with control subjects (3). Glipizide was reported to increase serum vitamin E and to decrease the level of lipid peroxidation markers in LDL and HDL particles with no change in the lipid profile in a randomized study with type 2 diabetes patients (21). Treatment of type II diabetics with retinopathy by glipizide increased antioxidant status such as the levels of plasma thiols and red blood cell superoxide dismutase activity and decreased the levels of lipid peroxides and platelet aggregation (22).

Marquie reported that glipizide at 10 mg/kg/day p.o. significantly inhibited the development of aortic and particularly coronary lesions induced by a high cholesterol diet (7). However, he did not study the oxidizability of LDL and the data on the degree of aortic atherosclerosis was not quantitative. Therefore, in this study, we examined the effects of glipizide on the experimental atherosclerosis and LDL oxidizability in the cholesterol-fed rabbits. In the present study, daily oral administration of glipizide (20 mg/kg/day) tended to inhibit the aortic atherosclerosis induced by feeding a 1% cholesterol diet for 10 weeks, although it did not affect diet-induced hyperlipidemia. The administration of glipizide also tended to inhibit the increase of serum TBARS by cholesterol feeding and increase the lag time of the conjugated diene formation of LDL subjected to in vitro oxidation although without significance. The maximal serum concentration of glipizide after oral administration of 40 mg or 80 mg in type II diabetic patients was 2.6 μg/ml or 4.6 μg/ml, respectively (23). The glipizide concentration in rabbit serum in this study was not much higher than clinical dose in Japan, which range between 40 mg/day and 160 mg/day. Scott et al. reported that glipizide acts as a general free radical scavenger in a dose-dependent manner in an in vitro assay system (18). Although more study is necessary, the present study suggests that glipizide may have antioxidative properties in vivo, and have further beneficial effects for the treatment of diabetes mellitus by inhibiting the oxidation of LDL.
