(Received 6 September, 2012; Accepted 21 September, 2012; Published online 30 November, 2012)

The present study was carried out to investigate the effect of vitamin E analogs, especially gamma-tocotrienol (γ-T3), on hepatic TG accumulation and enzymes related to fatty acid metabolism in three types of rat primary hepatocytes: (1) normal hepatocytes, (2) hepatocytes incubated in the presence of palmitic acid (PA), and (3) hepatocytes with fat accumulation. Our results showed that γ-T3 significantly reduced the TG content of normal hepatocytes. γ-T3 also increased the expression of carnitine palmitoyltransferase 1 (CPT1A) mRNA, and tended to reduce that of sterol regulatory element-binding protein 1c (SREBP-1c) mRNA. In addition, γ-T3 markedly suppressed the gene expression of both C/EBP homologous protein (CHOP) and SREBP-1c induced by PA. As these two genes are located downstream of endoplasmic reticulum (ER) stress, their suppression by γ-T3 might result from a decrease of ER stress. Moreover, γ-T3 suppressed the expression of interleukin 1β (IL-1β), which lies downstream of CHOP signaling. Taken together, our data suggest that γ-T3 might prevent hepatic steatosis and ameliorate ER stress and subsequent inflammation in the liver.

Key Words: tocotrienol, fatty liver, SREBP-1c, CPT1A, CHOP

On alcanolic fatty liver disease (NAFLD) is a clinical entity that includes a spectrum of conditions ranging from simple steatosis to steatohepatitis (NASH), cirrhosis, and liver cancer. NAFLD has been described as the hepatic manifestation of metabolic syndrome, and affected patients show histopathological changes similar to those of alcoholic fatty liver disease despite the absence of a history of excessive alcohol intake. The incidence of NAFLD has been increasing dramatically in not only Western countries but also the Asia-Pacific region.1,2 The so-called “two-hit theory” has been widely accepted as explaining the pathogenetic mechanism of NASH. The “first hit” is excessive fat accumulation in the liver induced by a high daily intake of energy and fat; thereafter, the “second hit” is characterized by induction of oxidative stress and inflammatory cytokines as a result of fat accumulation and deteriorating insulin resistance.

Natural vitamin E is divided into tocopherols (Toc) and tocotrienols (T3). T3 molecules differ from Toc molecules in that they possess three double bonds in the phytyl tail. These molecules are further divided into four isomers — α, β, γ, and δ — according to the number and position of the methyl group on the chroman ring. Although Toc is present in various foodstuffs such as nuts and seeds, green and yellow vegetables, and fish eggs, foodstuffs contain T3 are not as numerous, rice oil, palm oil, corn and rice bran being the main sources. T3 has been reported to decrease the plasma cholesterol concentration,3,4 to inhibit the growth of breast cancer,5 and to suppress angiogenesis.6 γ-T3 in particular has been shown to be a potent inhibitor of nuclear factor-κB (NF-κB) activation, leading to anti-angiogenic, anti-proliferative, pro-apoptotic, anti-metastatic, anti-inflammatory, and immunomodulatory effects.5

Recently, it has been reported that daily supplementation of vitamin E (800 IU/day) for 96 weeks ameliorated certain parameters of NASH, including the serum levels of alanine and aspartate aminotransferases (ALT and AST), hepatic steatosis, and lobular inflammation, although the mechanism responsible was unclear. Our previous study using rats showed that T3 was more effective than α-Toc or γ-Toc for suppressing the increases in plasma ALT and the hepatic content of triacylglycerol (TG) elicited by administration of carbon tetrachloride.7 Moreover, Burdeos et al.8,9 have reported that γ-T3 attenuated the accumulation of TG by regulating the gene and protein expressions of fatty acid synthase (FAS), carnitine palmitoyltransferase 1 (CPT1), and cytochrome P450 3A4 (CYP3A4) in the HepG2 human liver cell line.

On the other hand, some studies have shown that an increase of saturated fatty acids (SFAs) induces inflammation. For example, it has been reported that, in monocyte/macrophage cells, SFAs including lauric acid (C12:0) and palmitic acid (PA; C16:0) induce inflammation through the toll-like receptor-4 (TLR-4) signaling pathway, which is known as a receptor of lipopolysaccharide (LPS).9,10 In addition, PA has been reported to induce endoplasmic reticulum (ER) stress and subsequent apoptosis.9,10 Therefore, suppression of not only fat accumulation but also hepatic inflammation and ER stress induced by SFAs such as PA appears to be important for prevention of NASH.

In the present study we investigated the effect of γ-T3 on hepatic fat accumulation, which is the etiological basis of NASH and a complicating factor related to the progression of NAFLD. Using rat primary hepatocytes, we focused on how γ-T3 affected the TG content and expression of two genes related to fatty acid metabolism: CPT1A and sterol regulatory element-binding protein-1c (SREBP-1c). These effects were compared among three types of hepatocytes: normal hepatocytes, hepatocytes that had been cultured in the presence of PA, and hepatocytes that had accumulated fat. In addition, in rat primary hepatocytes cultured with PA, we investigated the effects of γ-T3 on expression of the genes for TLR-4, interleukin-1β (IL-1β), and C/EBP homologous protein (CHOP), which are related to inflammation and ER stress.

Materials and Methods

Materials. Gamma-T3 (98.7%) was kindly donated by Eisai Food & Chemical Co. Ltd. (Tokyo, Japan). Dietary vitamin E-stripped corn oil was purchased from Funabasi Farm Co. (Chiba, Japan). Dietary tert-butylhydroquinone, L(-)-cysteine, cholesterol, and sodium cholate were purchased from Wako Pure Chem. Ind. Ltd. (Osaka, Japan). Other purified foodstuffs were purchased from Oriental Yeast Co. Ltd. and Food & Chemical Co. Ltd. (Tokyo, Japan). Dietary vitamin E-stripped corn oil was purchased from Funabasi Farm Co. (Chiba, Japan). They were housed individually in stainless steel wire mesh cages and fed a commercial chow for three days. The temperature and humidity were controlled at 23 ± 2°C and 55 ± 5%, respectively, with a 12 h/12 h light-dark cycle. A seven-week-old rat used for preparation of normal primary hepatocytes was fed a high fat and cholesterol diet based on the AIN-93G diet, containing 20% (w/w) vitamin E-stripped corn oil, 1% (w/w) cholesterol, and 0.25% (w/w) sodium cholate, for two weeks. All experiments were conducted in accordance with the guidelines for the care and use of laboratory animals at Kanagawa Institute of Technology.

Experimental animals. Male Sprague-Dawley (SD)-IGS rats were purchased from Charles River Japan, Inc. (Kanagawa, Japan). They were housed individually in stainless steel wire mesh cages and fed a commercial chow for three days. The temperature and humidity were controlled at 23 ± 2°C and 55 ± 5%, respectively, with a 12 h/12 h light-dark cycle. A seven-week-old rat used for preparation of normal primary hepatocytes was fed a high fat and cholesterol diet based on the AIN-93G diet, containing 20% (w/w) vitamin E-stripped corn oil, 1% (w/w) cholesterol, and 0.25% (w/w) sodium cholate, for two weeks. All experiments were conducted in accordance with the guidelines for the care and use of laboratory animals at Kanagawa Institute of Technology.

Hepatocyte isolation and culture. After the rats had been laparotomized under diethyl ether anaesthesia, hepatocytes were collected by in situ perfusion of the liver with collagenase according to the method of Tenoutasse. Briefly, the livers were perfused with 200 ml of Hank’s buffer (pH 7.5), followed by the same volume of collagenase buffer (pH 7.5). The livers were then isolated and placed in DMEM-F12 (+) FBS medium (Sigma-Aldrich Co. LLC., Tokyo, Japan) containing penicillin/streptomycin (100 U/ml and 100 mg/ml), and immediately transferred to a clean bench. The filtered hepatocytes were washed twice with the medium, and then seeded at a density of 2 × 10^6 per 60-mm dish or 4 × 10^5 per well of a 12-well collagen-coated plate in DMEM-F12 (+) FBS medium supplemented with 10% fetal bovine serum (FBS), triiodothyronine (1 × 10^-6 M), hydrocortisone (5 × 10^-8 M), ethanolamine (1 × 10^-4 M), ornithine (4 × 10^-4 M), lactic acid (1.8 × 10^-3 M), and penicillin/streptomycin (100 U/ml and 100 mg/ml). The cells were grown at 37°C in a humidified atmosphere containing 5% CO2. The medium was changed after the first 4 h to remove unattached cells, and culture was then continued for 20 h.

At 24 h after cell seeding, 50 μM γ-T3 (final concentration) was added to the hepatocytes in DMEM-F12 (+) BSA medium containing 0.5% bovine serum albumin (BSA), insulin (1.75 × 10^-7 M), triiodothyronine (1 × 10^-6 M), ornithine (4 × 10^-4 M), lactic acid (1.8 × 10^-3 M), and penicillin/streptomycin (100 U/ml and 100 mg/ml), followed by incubation for 6 h. The medium was then changed to DMEM-F12 (+) BSA or the same medium supplemented with 0.5 mM PA (final concentration). The hepatocytes were then further incubated for 8 h for RNA analysis and for 18 h for measurement of cellular lipid.

PA-supplemented medium was prepared by adding PA (sodium salt) solution to DMEM-F12 (+) BSA medium at 0.5 mM (palmitic acid : BSA = 1 : 6.6 by molar ratio), equilibrated by shaking for 1 h at 37°C, and sterilized using a syringe filter before use.

Cell toxicity assay. The influence of γ-T3 and PA on cytotoxicity was examined by MTT assay. This assay is based on the ability of viable cells to metabolize water-soluble 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) into an insoluble formazan salt. After the seeded hepatocytes had been cultured in 12-well plates for 24 h, 10–50 μM γ-T3 and 0.025–0.5 mM PA were added to them separately, and incubation was continued for a further 24 h. The medium was then changed by adding 120 μl of MTT (5 mg/ml in PBS) to 1.2 ml of medium, and incubation was continued at 37°C for 4 h. After the MTT reaction, the medium was removed and the insoluble formazan crystals were dissolved in DMSO. Finally, the absorbance was measured at 570 nm.

RNA isolation and analysis. The hepatocytes in 12-well plates were incubated with γ-T3 for 6 h and then cultured under normal conditions or in the presence of PA for an additional 8 h as described above. Total RNA was extracted with RNA iso Plus regent (TAKARA BIO INC., Shiga, Japan). RNA purity was determined from the A260/A280 ratio. Total RNA was reverse-transcribed to complementary DNA (cDNA) using a high-capacity RNA-to-cDNA™ kit (Life Technologies Corporation, Tokyo, Japan). Next, the cDNA was quantified using a 7500 Fast Real-Time PCR system and a real-time PCR kit (TaqMan® Gene Expression Assays, Life Technologies Corporation) based on the manufacturer’s instructions, using β-actin as an endogenous control. Details of the primer/probe mixture of SREBP-1c, CPT1A, γ-TLR-4, IL-1β, CHOP, and C/EBP homologous protein are shown in Table 1.

Measurement of hepatocyte lipid content. The hepatocytes in 60-mm dishes were incubated with γ-T3 for 6 h and then cultured under normal conditions or in the presence of PA for an additional 18 h. After the cells had been washed with PBS twice, 1.5 mL of hexane:2-propanol (3:2 by vol.) solvent was added to the dishes, and the incubation was continued at 4°C for 15 min. The solvent was then collected in a test tube and the same extraction was repeated one more time. After centrifugation of the test tube and its content at 3000 rpm and 4°C for 5 min, 2 mL of the upper layer was collected, transferred to a centrifuge tube, and the solvent was distilled using a rotary evaporator. The extract was re-dissolved in 150 μl of 2-propanol and 1 ml of 2% Triton/2-propanol, then centrifuged at 3000 rpm and 4°C for 5 min. The final sample was obtained by emulsifying the upper layer at 70°C for 20 min. The concentration of TG was measured using TG E-test Wako (Wako Pure Chem. Ind. Ltd.). The amounts of hepatic lipids were expressed as mg lipid per mg protein. The protein fraction was collected with 0.5 M sodium hydroxide, and quantified by the Lowry method.

SREBP-1c: sterol regulatory element binding protein 1c, CPT1A: carnitine palmitoyltransferase 1, TLR-4: toll like receptor 4, IL-1β: interleukin 1β, CHOP: C/EBP homologous protein.
Oil red-O staining. Observations of lipid droplets in normal and fat-accumulated hepatocytes were made using oil red-O staining. After hepatocytes seeded on 60-mm dishes had been cultured for 48 h, they were washed with PBS, and then fixed with 10% formalin solution. The hepatocytes were then washed with distilled water, and incubated with 0.3% oil red-O in 60% 2-propanol for 30 min. The stained hepatocytes were washed again with distilled water several times, and then observed using a light microscope.

Statistical analysis. All data are presented as mean ± SD. Significance of differences in assay values was evaluated using one-way ANOVA, followed by the Bonferroni multiple comparison post-hoc test or independent t test, using SPSS ver.11.0 for Windows. Differences at p<0.05 were considered to be statistically significant.

Results

Cytotoxicity of γ-T3 and PA. First, the cytotoxicity of γ-T3 or PA on rat primary hepatocytes was assessed by incubation of the cells with various doses for 24 h, and then measuring their viability using the MTT assay. Hepatocytes incubated with γ-T3 (50 μM) or PA (0.5 mM) showed no reduction of viability (105 ± 1.26% and 103 ± 1.81% vs control, respectively). Therefore, these concentrations of γ-T3 and PA were used in the subsequent studies.

Effects of γ-T3 on TG content and expression of mRNAs related to hepatic TG metabolism in normal hepatocytes. Hepatic TG content was significantly reduced by γ-T3 (50 μM) in normal primary hepatocytes (Fig. 1a). To elucidate the effect of γ-T3 on enzymes related to fatty acid metabolism, especially SREBP-1c and CPT1A, expression of their mRNAs in the hepatocytes was measured. It was found that expression of SREBP-1c mRNA tended to be reduced by γ-T3 (Fig. 1b) whereas that of CPT1A mRNA was significantly increased (Fig. 1c). This suggested that γ-T3 might accelerate TG catabolism and suppress TG synthesis in the liver.

Effects of γ-T3 on TG content and expression of mRNAs related to hepatic TG metabolism in hepatocytes incubated with PA. Next, we examined the effect of γ-T3 on PA-induced TG accumulation in normal hepatocytes. γ-T3 did not suppress the TG accumulation elevated by PA addition (Fig. 2a). However, γ-T3 significantly suppressed the increase of SREBP-1c mRNA expression induced by PA (Fig. 2b). Expression of CPT mRNA was also increased by PA, and no differences were observed after addition of γ-T3 (Fig. 2c).
These results suggested that γ-T3 did not suppress the accumulation of TG caused by rapid inflow of PA into hepatocytes. However, γ-T3 suppressed the expression of SREBP-1c mRNA induced by addition of PA.

**Development of a model of fat accumulation in hepatocytes.** In order to compare the effects of γ-T3 between normal liver and fatty liver, we attempted to develop a model of fat accumulation in primary hepatocytes. The hepatocytes were obtained by perfusing the liver of a fatty rat that had been fed a high fat and cholesterol diet for two weeks. The TG content of fatty hepatocytes was found to be dramatically increased in comparison with normal hepatocytes (Fig. 3a). In addition, light microscopy after oil red-O staining demonstrated a number of red-stained fat droplets in fatty hepatocytes (Fig. 3b). Therefore, we decided to assess the effects of γ-T3 using these fatty hepatocytes.

**Effects of γ-T3 on TG content and expression of mRNAs related to hepatic TG metabolism in fatty hepatocytes.** When fatty hepatocytes were cultured with γ-T3 at 50 μM (final concentration), their TG content was not reduced, unlike the outcome in normal hepatocytes (Fig. 4a). In addition, γ-T3 did not affect the expression of mRNA for either SREBP-1c or CPT1A (Fig. 4b and c). This suggested that γ-T3 was unable to attenuate the excessive accumulation of lipids in hepatocytes.

**Effects of γ-T3 on expression of mRNAs related to inflammation and ER stress in hepatocytes incubated with PA.** We also investigated the anti-inflammatory effect of γ-T3 on primary hepatocytes that had been incubated with PA. Whereas γ-T3 elicited no significant change in the expression of TLR-4 mRNA (Fig. 5a), it significantly suppressed the expression of CHOP mRNA, a marker of ER stress, that had been stimulated by addition of PA (Fig. 5b). Interestingly, γ-T3 reduced the expression of IL-1β mRNA irrespective of whether or not hepatocytes had been cultured in the presence of PA (Fig. 5c).

**Discussion**

In the present study using rat primary hepatocytes, we examined the effects of γ-T3 on TG content and the expression of genes for enzymes involved in fatty acid metabolism (SREBP-1c and CPT1A) and factors related to ER stress and inflammation (TLR-4, CHOP and IL-1β). These effects were compared among 1) normal hepatocytes, 2) hepatocytes cultured with PA, and 3) hepatocytes with fat accumulation in order to investigate any effects of γ-T3 relevant to the prevention or amelioration of fatty liver disease.

Our result showed that γ-T3 reduced the TG content of normal hepatocytes (Fig. 1a). Using SD rats, we had previously demonstrated the suppressive effect of a T3 mixture on hepatic TG accumulation resulting from administration of carbon tetrachloride. Burdeos et al. have also reported that a T3 mixture from rice bran reduced hepatic TG in F344 rats, and also that γ-T3 at 10–15 μM decreased the TG content of HepG2 cells. They suggested that the TG-lowering effect of γ-T3 in HepG2 cells could be partly explained by its ability to down-regulate the hepatic fatty acid synthase gene (FAS) and up-regulate β-oxidation genes (CPT1A and CYP3A4). In the present study we...
confirmed the TG-lowering effects of γ-T3 in rat primary hepatocytes. However, we also found another mechanism by which γ-T3 reduced the hepatic TG content. In normal rat primary hepatocytes, up-regulation of CPT1A and down-regulation of SREBP-1c were considered to be the main mechanisms responsible for the TG-lowering effect (Fig. 1 b and c). CPT1, located in mitochondria, is the rate-limiting enzyme for fatty acid oxidation. It has three isoforms, CPT1A, CPT1B, and CPT1C, and CPT1A is the isoform known to exist in the liver. On the other hand, SREBP1s are located on the ER membrane, and operate as nuclear transcription factors. There are three isoforms, SREBP-1a, -1c, and -2. SREBP-1c in particular has a greater role in regulating fatty acid synthesis than it does in cholesterol synthesis. In addition, Yahagi et al.(15) have shown that absence of SREBP-1 markedly reduced the hepatic TG content of leptin-deficient (Lep−/−) mice relative to Lep+/+ mice. Furthermore, using wild type and SREBP-1c-null mice, Ji et al.(16) demonstrated that the predominant mechanism of hepatic TG accumulation in mice fed alcohol intragastrically required the presence of SREBP-1c. Therefore, it appears that SREBP-1c plays important roles in the synthesis of not only fatty acid but also TG. Moreover, in a human clinical study, Kohjima et al.(17) have evaluated the expression of fatty acid metabolism-related genes in patients with NAFLD (n = 26) and normal liver (n = 10), and found that in NAFLD SREBP-1c gene expression was increased and CPT1A gene expression was decreased. In other words, in order to ameliorate NAFLD, down-regulation of the SREBP-1c gene and up-regulation of the CPT1A gene appear to be very important. Therefore, our present data support the notion that γ-T3 has a capacity to ameliorate NAFLD through regulation of these genes.

To examine this possibility in greater depth, we compared the effects of γ-T3 among three types of hepatocytes: 1) normal hepatocytes; 2) hepatocytes cultured with PA, and 3) hepatocytes that had accumulated fat. In normal hepatocytes γ-T3 might be expected to suppress TG synthesis through down-regulation of SREBP-1c, and then activate beta-oxidation of remaining fatty acid by up-regulation of CPT1A. However, in a situation where large amounts of free fatty acids are flowing into hepatocytes, TG synthesis would advance at a pace faster than suppression of SREBP-1c by γ-T3. Furthermore, in a situation where TG accumulation in hepatocytes had already advanced, any improvement of steatosis by γ-T3 might be difficult because of the inability of SREBP-1c and CPT1A to control the form of TG.

On the other hand, acceleration of very low-density lipoprotein (VLDL) secretion is also important for reduction of the hepatic TG content. In this study, we examined the expression of apolipoprotein B (ApoB) mRNA, but found it was unaffected by γ-T3 (data not shown). By contrast, Zaidan et al. have shown that γ-T3 and δ-T3 down-regulated the protein expression of both ApoB100 and diacylglycerol acyltransferase 2 (DGAT2) in HepG2 cells. As DGAT2 plays a key role in TG biosynthesis, and ApoB plays a role in VLDL synthesis in the liver, down-regulation of these proteins would be considered to ameliorate arteriosclerosis. However, in the context of fatty liver disease, excessive suppression of ApoB expression would not be desirable. At the present time, it remains to be clarified how γ-T3 is involved in VLDL synthesis and secretion. Therefore, further studies will be needed to examine the effect of γ-T3 on secretion of TG from the liver to plasma.

In this study, we also found that γ-T3 attenuated the increased expression of CHOP elicited by culture of hepatocytes in the presence of PA (Fig. 5b). CHOP signaling is induced by ER stress, which in turn leads to apoptosis. Endo et al.(18) have reported that CHOP plays an essential role in TLR-4 pathway signaling during inflammation, and suggested that treatment with LPS would stimulate TLR-4, thus inducing ER stress. Meanwhile, some previous studies have demonstrated that SFAs such as PA induce inflammation through the TLR-4 signaling pathway, as in the case for LPS.(9,19) Furthermore, Wei et al.(10) have shown that PA-induced ER stress and subsequent apoptosis in liver cells are mediated by CHOP signaling. Our present result suggested that PA increased CHOP signaling by inducing ER stress, and we found that γ-T3 markedly suppressed the increase of ER stress that had been induced by PA. However, TLR-4 was not significantly changed (Fig. 5a), perhaps because of a signaling time lag. With regard to ER stress and inflammation, Endo et al.(19) have reported that expression of CHOP induced by ER stress activated caspase-11 and -1 signaling, and then increased the activation of pro-IL-1β to mature IL-1β in lung cells. Therefore, ER stress would induce further production of inflammatory cytokines, including IL-1β, and in fact we clarified that γ-T3 reduced the gene expression of IL-1β irrespective of whether PA was present or absent (Fig. 5c). These results suggested that γ-T3 suppressed the inflammatory cytokines induced by TLR-4 and CHOP signaling. At the present time, however, it is unclear why γ-T3 reduced the expression of the IL-1β gene under normal conditions. It will therefore be necessary to confirm how γ-T3 directly affects IL-1β gene expression.

In attempting to address the relationship between ER stress and TG accumulation, Wand et al.(20) have demonstrated that ER stress...
activates SREBP-1c, and that this is implicated in β-cell glucolipo-toxicity. That is, ER stress induces TG accumulation through an increase of SREBP-1c. Taken together, the data suggest that suppression of ER stress is very important for breaking the vicious cycle between fat accumulation and inflammation in the liver, and that γ-T3 controls fatty acid metabolism and inflammation through amelioration of ER stress.

In summary, we have clarified that γ-T3 significantly reduces the TG content of normal rat primary hepatocytes through up-regulation of CPT1A and down-regulation of SREBP-1c. We have also shown that γ-T3 suppresses the gene expression of both SREBP-1c and CHOP induced by PA. As these two genes are located downstream of ER stress, the suppressive effects of γ-T3 on SREBP-1c and CHOP might result from a decrease of ER stress. Our present findings suggest that γ-T3 might prevent steatosis and ameliorate hepatic ER stress and subsequent inflammation.
