To investigate the Lagrangian behavior of turbulent eddies in fully turbulent pipe flow, two point space-time correlations were measured by the electrochemical method; s-s correlation between the wall shear stresses spaced along the axial direction, s-u correlation between the wall shear stress and the local axial velocity in the same cross section, and u-u correlation between the local axial velocities in the same cross section.

The correlation for time lag, defined as the delay time at which the correlation function becomes maximum, has been obtained for each cross correlation.

The axial distribution of the time lags in the s-s correlation demonstrates that the axial velocity of turbulent eddies near the wall is 0.455 times the average velocity but is not proportional to the friction velocity as reported by Py.

A model on transmission of turbulent disturbance is proposed here upon which the transmission velocities in the radial direction have been obtained from the s-u and u-u correlations respectively. The transmission velocity from the s-u correlation is proportional to \((y/R)^{0.2}\), which corresponds to the radial velocity of an inrushing eddy. On the other hand, the transmission velocity in the bulk region obtained from the u-u correlation decreases towards the center.

Introduction

A complete theory of the phenomena of turbulent diffusion is not available even in the simplest case of homogeneous isotropic turbulence. Some experimental studies on dispersion of scalar quantities, such as temperature or concentration, in turbulent flows have been carried out by Corrsin\cite{1} and others. In spite of its importance, little is known about the behavior of turbulent eddies themselves.

To determine the spatial variations of the turbulent structure and the statistical character of the turbulent convected frame, a two point space-time correlation technique has been utilized in a turbulent boundary layer by Blackwelder and Kovasny\cite{2} and Favre et al.\cite{3}, in a two-stream mixing layer by Jones et al.\cite{4}, and in pipe flow by the authors below.

This technique is applicable to measurements of the longitudinal velocity of disturbance near the wall with imbedded two point detectors spaced along the mean flow direction. Show and Hanratty\cite{5} measured electrochemically the local mass transfer rate at the wall and estimated the convective velocity of disturbance moving downstream \(U_s^+\sim 1\). Liu\cite{6} used the streaming potential measurements in a turbulent pipe flow and obtained a disturbance velocity of about 0.7 to 0.8 times the bulk average velocity. Py\cite{7} used the electrochemical wall shear stress meters and found that the disturbance velocities \(U_s^+\) depended on the distance between two point electrodes and seem to approach a constant, \(U_s^+ \sim 6.3\), as the distance decreases.

On the other hand, Eckelmann\cite{8} measured the space-time correlation between fluctuations of velocity gradient at the wall and those of local velocity at \(y^+\) apart from the wall. He found that the correlation had very high values in the range of \(y^+\leq 5\) while having some time lags. Based on the simple penetration model, the transmission velocity towards the wall was estimated as \(Y_s^+ = 1\) for \(y^+ \leq 5\). This correlation gives a better understanding to the turbulent structure near the wall, together with the visual investigations by Kim et al.\cite{9} and Corino and Brodkey\cite{10} who found intermittent bursting and inrushing phenomena.

The present work is an effort to clarify the statistical behavior of turbulence by applying two point space-time correlation technique to the velocity and shear stress fluctuations in a fully developed turbulent pipe flow; also, a transmission model of turbulent disturbance will be proposed, upon which the transmis-
1. Experimental Equipment and Techniques

The investigation was conducted in a straight plastic pipe of 67 mm diameter and the test section had an $L/D=60$, where the flow was considered as being fully developed for $Re>10^4$.

For measurements of fluid velocity and wall shear stress, the diffusion controlled redox reaction of ferri-ferro cyanide ions was utilized.

Twelve point electrodes, 0.3 mm Pt, imbedded at the wall of the test section for measurement of the cross correlation between local wall shear stresses were arranged spaced along a line parallel to the pipe axis, the separation of which were 0.134, 0.273, 0.457, 0.758, 0.985, 1.266, 1.640, 2.046, 2.560, 3.385, 4.385 cm (center to center).

For measurement of fluid velocity, a blunt-nose type electrode, 0.2 mm Pt, was used.

For the cross correlations between fluctuations of wall shear stress, $s$, and velocity, $u$, at a distance $y$ from the wall, a blunt-nose electrode was traversed in the radial direction at the same cross section with the wall shear stress meter as shown in Fig. 1. For the measurement of $s-u$ correlations, the range of $Re$: 38200, 76400, 114600.

For the cross correlations of two velocity fluctuations at $y_r$ and $y_r+\Delta y$, the reference electrode was fixed at $y_r$ and the other was traversed further away from the wall than the reference one. The measurements were carried out at $y_r$ of 3.92, 7.27, 10.65, 13.74, 17.35 mm and the range of $\Delta y$ to be 0.89–15.7 mm at $Re$ of 89600 only.

The liquid used was a solution of 0.01 mol/l $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$, and 1 mol/l NaOH as a supporting electrolyte, and held at a temperature of $30^\circ\pm0.02^\circ$C. The properties of the solution: $\rho=1.039$ g/cm$^3$, $\mu=0.905$ cp.

The experimental data were recorded on a FM tape recorder (TEAC R-400), and the correlations were computed by a real time digital correlator (TEAC C-100) with the maximum delay time of 94 times the sampling period. The data were sampled at the periods of 0.4, 1, 2 msec and the correlations were computed by the moving average method with the weight of $2^{-\alpha}$ ($\alpha=10, 11, 12$).

2. Experimental Results

Friction factor calculated from the time-averaged wall shear stress measured by the imbedded point electrode coincided with the Blasius empirical equation.

Velocity profile measured by a blunt-nose electrode was well represented by the universal velocity profile for each run.

![Fig. 1 Test section](image1)

![Fig. 2 Distributions of relative turbulence intensities of local axial velocity](image2)

Turbulent intensity distributions in the bulk region obtained from the current fluctuations of the blunt-nose electrode are shown in Fig. 2, and compared with the data of Laufer at $Re_{max}=50000$. Fairly good agreement can be seen.

Two point space-time correlations, i.e., $s-s$ correlation as a function of the separation $x$ and the delay time $\tau$, $s-u$ correlation as one of the distance $y$ and $\tau$, and $u-u$ correlation as one of the position of reference electrode $y_r$, the radial separation of electrodes $\Delta y$ and $\tau$ were measured respectively, these are defined below. A typical example of $s-u$ correlation is shown in Fig. 3, in which the delay time maximizing the correlation at a fixed $y$ gives the time lag $\tau_y$.

$s-s$ correlation between fluctuations of wall shear stress measured by two point electrodes with the longitudinal separation $x$, is defined as

$$R_{ss}(x, \tau) = \frac{\langle s(x, \tau) \cdot s(x+x, \tau+\tau) \rangle}{\langle s^2(x, \tau) \cdot s^2(x+x, \tau) \rangle}^{1/2}$$

The < > denotes the long time average of a statistically stationary quantity.

From the delay time τ_a at which R_a becomes maximum, the axial velocity of disturbance near the wall can be apparently obtained.

A plot of x/τ_aU_s (= U_s/U) vs. x^+ gave a better correlation than x/τ_aU_s (= U_s') vs. x/A_s correlated by Py<sup>9</sup>, where U_s is the bulk mean velocity. However, it should be noted that though the ranges of Re for these experiments were different, the correlation curves show the similar tendencies; that is, the disturbance velocity U_s approaches a constant value as decreasing separation and U_s increases as x increases, as shown in Fig. 4.

In the present work, the constant value of U_s/U is obtained approximately as 0.455 for x^+ < 330.

Table 1 compares the available data on disturbance velocity. The results of this work agree with those of Py, and shows that the disturbance velocity corresponds to the local mean velocity at y^+ = 9. The rather large value of Liu's data<sup>9</sup> may be due to the large separation of detectors. The too small values given by Hanratty<sup>10</sup> are presumably caused by the difference between the measuring methods of shear stress and of mass transfer.

The u-u correlation between fluctuations of wall shear stress and local velocity at a distance y from the wall in the same cross section (x=x_0), is defined as

\[
R_{uu}(y_r, \tau) = \frac{\langle u(x_0, y_r+\Delta y, t) \cdot u(x_0, y_r, t+\tau) \rangle}{\langle u^2(x_0, y_r+\Delta y, t) \cdot u^2(x_0, y_r, t) \rangle}^{1/2}
\]

The signals from the traversed electrode (\Δ y > 0, further from the wall than the reference one) always advance to the corresponding signals from the reference electrode. Denoting τ_u the time lag maximizing R_uu at fixed y_r and \Δ y as same above, τ_u becomes a function of the position of electrodes and the flow characters at y_r and y_r+Δ y.

In the range of \Δ y/R > 0.05, a proper correlation has been found in the relation (τ_uU/R)(y_r/R) vs. (Δ y/R) as shown in Fig. 6, which is expressed by

\[
(\tau_u U/R)(y_r/R) = 5.71(\Delta y/R)^{0.66}
\]
yr/R<0.5lS, dy/R<0.01, at only one Re of 89600. In the range of dy/R<0.05, the data scatter widely due to an uncertainty in measuring small values of τ and a small inevitable longitudinal separation between the tips of traversed and reference electrodes.

3. Transmission Mechanism of Turbulent Disturbance

Based on the experimental results that the fluctuating signals from the electrode at the farther distance from the wall always advance to the corresponding signals from the inner electrode as mentioned above, there is proposed a model concerning the transmission mechanism of turbulent disturbance.

Suppose an original disturbance at x, y, being convected in the flow direction at the local mean velocity U according to the Taylor's hypothesis, and at the same time being transmitted in the radial direction by an eddy motion as shown in Fig. 7. Then, the time lag in the s-u correlation is given by the difference between the time of the original disturbance reaching to the U-probe (x=0, y) and the corresponding one arriving at the S-probe (x=0, y=0).

Because the path line of the eddy is given by
dt=dx/U=dy/Vt (6)
then the time lag τ is expressed as
τ=\int_0^{y} \frac{1}{Vt} dy - \int_0^{y} \frac{U}{U_1} dy = \int_0^{y} \frac{1}{Vt} \left(1 - \frac{U}{U_1}\right) dy
(7)
and also the time lag τ is similarly
τ=\int_0^{y} \frac{1}{Vr} dy - \int_0^{y} \frac{U}{U_1} dy = \int_0^{y} \frac{1}{Vr} \left(1 - \frac{U}{U_1}\right) dy
(8)
Thus τ depends on y and τ on y and y, or dy.

The transmission velocity Vt is derived from Eq. (7) as
\frac{1}{Vt} = \frac{d}{dy} \frac{dτ}{dy}
(9)
and from Eq. (8) as
\frac{1}{Vr} = \frac{d}{dy} \frac{dτ}{dy}
(10)
Since the position of U-probe, y, is arbitrary, the suffix “1” may be dropped out.

From the s-u correlation, Eq. (3) leads to the expression for the transmission velocity in the y direction by combining the universal velocity profile, \( U^+ = 2.5 \ln y^+ + 5.5 \), as follows
\( Vt^+ = 1.06(y/R)^{0.3} \) (11)
Eckelmann\(^3\) estimated the transmission velocity across the viscous sublayer based on the simple transmission model, which gave simply
\( Vt^+ = dy^+/dτ^+ = 1 \)
(12)
This relation leads to \( Vt^+ = 0.5 \) according to the definition in this study, Eq. (7).

From the u-u correlations, the transmission velocity in the bulk region is derived from Eq. (5) as follows
\( Vt^+ = (y/R)^{0.7} [3.79(y/R)^{0.66} + 0.66(y/R)(dy/R)^{-0.34}] \) (13)

The transmission velocities \( Vt^+ \) calculated by Eqs. (11) and (13) are shown in Fig. 8. \( Vt^+ \) obtained from
the s-u correlation increases with increasing \( y \), on the other hand \( V_t^* \) obtained from the u-u correlation decreases on the whole while having a weak dependency on \( y_r \). The opposite behaviors of transmission velocities which seem strange at first sight may be explained by introducing a dynamic process of eddies' motion based on the visual investigations\(^2\)\(^6\), which is shown in Fig. 9.

In the bulk region, eddies of relatively large scale move downstream while intermingling with each other. If an eddy has a sufficient radial velocity, it inrushes towards the wall and a part of which breaks down and creates a bursting eddy towards the center due to the strong interaction with the retarded flow near the wall. The remaining unbroken eddy is swept along the wall or by turning its direction slightly to the center by the following inrushing eddies, and then diffuses to the bulk region while intermingling with the eddies in that region.

Consider here the different behaviors between the transmission velocities \( V_t \) from the s-u and u-u correlations in Fig. 8 with reference to the dynamic process mentioned above. The transmission velocity \( V_t \) defined here may be considered corresponding to the statistical difference between the inward velocity \( V_i \) and outward velocity \( V_o \) of eddies, \( V_t = V_i - V_o \).

In the s-u correlation, the signals of inrushing, bursting and leaving eddies must have been measured. Of course, a proper conditional sampling of signals will give results corresponding to the bursting phenomena, that is the disturbance goes from the wall region to the bulk region (\( V_i < 0 \)). However, from the results of \( V_i > 0 \), it is considered that the inrushing disturbance has predominantly been observed for the long time intervals since the occurrence of bursting is very intermittent. Consequently, the transmission velocity \( V_t \) corresponds mainly to the inrushing velocity, and it decreases towards the wall due to the wall effect.

In the u-u correlation, the reference electrode nearest the wall was set at \( y_r/R = 0.117 \) or \( y^+ = 250 \), where the strong bursting phenomena might have finished according to the visual study by Corino et al.\(^2\). In that case the U-probes would have measured mainly the signals of inward and outward eddies.

As mentioned above, the leaving eddy increases its velocity towards the center with intermingling with the eddies in the bulk region. Consequently the transmission velocity \( V_t = V_i - V_o \) decreases towards the center.

In Fig. 8, the transmission velocities are also compared with the intensity of radial component of velocity \( v \) measured by Laufer\(^7\). The comparison of these quantities may have less meaning, since the transmission velocity \( V_t \) from the s-u correlation corresponding to the inrush velocity is Lagrangian but the intensity \( v \) is Eulerian. However, it is interesting that these values are of the same order of magnitude.

**Summarising Remarks**

A two point space-time correlation technique was applied to measuring \( R_{ss}(x,\tau), R_{su}(y,\tau), R_{uu}(y_r,\Delta y,\tau) \) in fully developed turbulent pipe flow.

The representation for the time lags \( \tau_x, \tau_y \) and \( \tau_v \) better than the previous reported ones, have been shown in Fig. 4, 5 and 6, and the correlating equations, Eq. (3) for \( \tau_x \) and Eq. (5) for \( \tau_v \) have been obtained.

The variation of the time lag \( \tau_v \) in the flow direction revealed the disturbance velocity \( U_* \) along the wall as being proportional to the cross sectional average velocity \( \bar{U} \).

Based on the variations of time lags \( \tau_x \) and \( \tau_v \) in the radial direction, the transmission model of turbulent disturbance has been proposed on which the transmission velocities have been derived as Eqs. (11) and (13). The transmission velocity from the s-u correlation, Eq. (11), is proportional to \( (y/R)^{0.3} \) and corresponds to the velocity of inrushing eddy. On the other hand, Eq. (13) from the u-u correlation gives the transmission velocity in the bulk region, which decreases towards the center. This opposite behavior shows the further importance of measuring the u-u correlations in the wall region. The velocity of inrushing eddy is the same order as the intensities of radial velocity component, though those are Lagrangian but these are Eulerian.

In this study, the transmission mechanism of turbulent disturbance has been discussed only from the time lags maximizing the correlation functions. To understand fully the Lagrangian behavior of turbulent eddies, it is necessary to measure additional correlations such as \( R_{uu}(x,y,\tau) \) and discuss the values of correlation functions in addition to the time lags.

**Nomenclature**

- \( D \) = diameter of pipe \([\text{cm}]\)
- \( L \) = length from entrance \([\text{cm}]\)
- \( R \) = radius of pipe \([\text{cm}]\)
- \( Re \) = Reynolds number \( = 2\pi R \bar{U} \mid \mu \) \([-]\)
- \( Re_{uax} \) = \( 2\pi RU_{uax} \mid \mu \) \([-]\)
$R_{ss}$ = correlation between fluctuations of wall shear stresses, defined by Eq. (1) 

$R_{sv}$ = correlation between fluctuations of wall shear stress and local velocity, defined by Eq. (2) 

$R_{uu}$ = correlation between fluctuations of local velocities, defined by Eq. (4) 

$s$ = fluctuation of wall shear stress [g/cm·sec²] 

$t$ = time [sec] 

$U$ = local mean velocity [cm/sec] 

$U$ = cross sectional average velocity [cm/sec] 

$U_{max}$ = maximum velocity [cm/sec] 

$U_*$ = disturbance velocity of eddy along the wall [cm/sec] 

$u$ = fluctuation of local axial velocity [cm/sec] 

$u^*$ = friction velocity [cm/sec] 

$V_i$ = inward velocity of eddy to the wall [cm/sec] 

$V_o$ = outward velocity of eddy from the wall [cm/sec] 

$V_i$ = transmission velocity of turbulent disturbance in the radial direction, defined by Eqs. (12) [cm/sec] 

$V_i$ = transmission velocity of turbulent disturbance in the radial direction, defined by Eq. (6) [cm/sec] 

$y$ = fluctuation of local radial velocity [cm/sec] 

$x$ = longitudinal distance [cm] 

$x^*$ = $\rho x u^*/\mu$ [-] 

$y$ = radial distance from the wall [cm] 

$y_r$ = distance of reference probe from the wall [cm] 

$y^*$ = $\rho y u^*/\mu$ [-] 

$A_x$ = macro scale given by Py [cm] 

$\rho$ = density [g/cm³] 

$\mu$ = viscosity [g/cm·sec] 

$\tau$ = time lag [sec] 

$\tau_x$ = time lag maximizing $R_{ss}$ [sec] 

$\tau_y$ = time lag maximizing $R_{sv}$ [sec] 

$\tau_u$ = time lag maximizing $R_{uu}$ [sec] 

$\tau^*$ = $\tau u^*/\nu$ [-]
