Evidence is increasing for small vessel remodeling and disturbance of endothelium-dependent vasodilation in diabetic patients. Insulin increases vascular wall thickening and produces endothelial dysfunction. Troglitazone, a new insulin-sensitizer antidiabetic agent, is considered to reduce plasma insulin level and the present study assessed its effect on the coronary circulation of the patients with non-insulin-dependent diabetes mellitus (NIDDM). Analysis of the myocardial washout rate with adenosine triphosphate-stress thallium-201 scintigraphy was used to estimate coronary circulation, and for estimation of insulin sensitivity, the homeostasis model insulin resistance index (HOMA-R) was calculated. Patients were treated with monotherapy of either troglitazone (200 mg bid, n=12) or glibenclamide (2.5 mg daily, n=12) for 3 months. Age-, sex- and risk factors-matched subjects without NIDDM were employed as a control. Fasting plasma glucose and hemoglobin A1c were similarly decreased by troglitazone or glibenclamide. Plasma insulin level (pmol/L) decreased from 66.6±10.8 to 39.0±7.2 with troglitazone, but was unchanged by glibenclamide (58.8±7.2 to 66.0±10.8). The diabetic groups had a significantly lower washout rate than controls, which was improved by troglitazone, but not by glibenclamide. In addition, the increase in washout rate correlated significantly with the decrease in HOMA-R in the troglitazone group. In conclusion, troglitazone can restore coronary circulation by improving insulin resistance in patients with NIDDM. (Jpn Circ J 2001; 65: 487–490)

Key Words: Coronary circulation; Insulin resistance; Non-insulin-dependent diabetes mellitus; Troglitazone; Washout rate

Patients with non-insulin-dependent diabetes mellitus (NIDDM) frequently have signs of myocardial ischemia and congestive heart failure (diabetic cardiomyopathy) in the absence of obstructive coronary disease. It has been reported that wall thickening and lumen narrowing of the intramural coronary microvasculature may result in inadequate coronary flow reserve capacity by reducing the maximal area of the coronary microcirculation. In addition, evidence is increasing for disturbance of endothelium-dependent vasodilation in conduit as well as resistant coronary arteries in patients with NIDDM. Thus, abnormal coronary circulation may contribute to the myocardial ischemia or diabetic cardiomyopathy.

The pathophysiology of NIDDM is complex, but insulin resistance is a characteristic feature and contributes importantly to the hyperglycemic diabetic state. Insulin has various biological actions on the vessel wall, such as proliferation of vascular smooth muscle cells and enhancement of the intracellular Na+/H+ pump. Therefore, hyperinsulinemia caused by insulin resistance may increase wall thickening and produce endothelial dysfunction.

Troglitazone is a newly developed antidiabetic agent that improves insulin resistance and its anti-diabetic and insulin suppressive effects have been confirmed in patients with NIDDM. The present study assessed the effect of troglitazone on coronary circulation in patients with NIDDM, using adenosine triphosphate disodium (ATP)-stress thallium-201 myocardial scintigraphy, which has been reported to be an useful tool for non-invasive assessment of coronary perfusion and coronary flow reserve.

Methods

Study Patients

The study group consisted of 24 outpatients with NIDDM (15 men, 9 women; aged 45–71 years (mean±SD) 60±9 years). All patients had angiographically normal coronary arteries. The enrollment criteria of NIDDM were fasting plasma glucose (FPG) ≥7.00 mmol/L and a fasting insulin level (IRI) ≥30 pmol/L on at least 2 separate visits. In addition, NIDDM had been newly diagnosed in all the patients, who had never been treated with antidiabetic drugs. Patients with left ventricular hypertrophy, left ventricular dysfunction, a history of myocardial infarction, or valvular heart disease were excluded from the study. We also selected 12 subjects without NIDDM, matched in age, sex, and risk factors except DM as a control group.

Study Protocol

Patients were randomized to 2 groups for either troglitazone therapy (200 mg bid, n=12) or glibenclamide therapy (2.5 mg daily, n=12), and the drugs were administered orally for 3 months. Exercise and dietary prescriptions were unchanged during the study. FPG was measured every 4 weeks and IRI was measured by radioimmunoassay before

and after the treatment with troglitazone or glibenclamide. For estimation of insulin sensitivity, the homeostasis model insulin resistance index (HOMA-R) (FPG × IRI/22.5) was calculated.\textsuperscript{22,23} ATP-stress \textsuperscript{201}TI myocardial scintigraphy was conducted before and after the treatments. The protocol of the study was approved by the Investigational Review Board of the hospital, and the study was conducted in compliance with the Helsinki Declaration. All subjects gave informed consent before enrollment into the study.

**Echocardiography**

Left ventricular wall thickness and dimensions, and left ventricular mass were calculated from 2-dimensional echocardiograms using a previous described algorithm, according to the recommendations of the American Society of Echocardiography.\textsuperscript{24} Left ventricular ejection fraction was also calculated according to the American Society of Echocardiography criteria by the area-length method.\textsuperscript{25}

**ATP-Stress Thallium-201 Myocardial Scintigraphy**

The details of the procedure have been described previously.\textsuperscript{17} ATP was infused for 3 min through a peripheral venous catheter for 5 min at the rate of 0.16 mg·kg\textsuperscript{-1}·min\textsuperscript{-1}. Next, 111 MBq (3 mCi) of \textsuperscript{201}TI were injected as a bolus into another venous site, and the infusion of ATP was continued for an additional 2 min. \textsuperscript{201}TI imaging was performed using a large field of view rotating gamma camera equipped with a low-energy, high-resolution collimator interfaced to a computer (Toshiba GMS-550U, Tokyo Japan). Tomographic reconstruction at 7 min (initial image) and 4 h (delayed image) after \textsuperscript{201}TI injection was performed and quantified by computerized 2-dimensional polar (Bull’s eye) maps of radionuclide activity. The myocardial washout rate was defined as the percent change in activity from the initial to the delayed images within the left ventricle and calculated as: washout rate (\%) = (A–B)/A × 100, where A = average count/pixel in the left ventricle on the initial image and B = average count/pixel in same region on the delayed image.

Effect of Troglitazone on Coronary Circulation in NIDDM

Because the initial 201Tl distribution reflects a relative rather than an absolute reduction in myocardial blood flow, no myocardial abnormality was seen in diabetic patients in this study, all of whom may have homogeneous underperfusion of all myocardial regions. The myocardial washout rate has been analyzed in a nonrelative fashion to indicate diffuse hypoperfused myocardium that shows no perfusion defects.19–21,26 We evaluated the relationship between the myocardial washout rate and coronary flow reserve in the study patients within 2 weeks before randomization. According to our previous report,18 coronary flow reserve is obtained from the ratio of ATP-induced (intravenous infusion at rate of 0.16 mg·kg−1·min−1) hyperemic to baseline time-averaged peak velocity, and as shown in Fig 1, a significant relation was observed (r=0.71, p<0.01). Therefore, washout rate was used as the non-invasive evaluation of coronary circulation.

Statistical Analysis
Data are expressed as mean±SEM. Differences between 2 groups were assessed by paired t test with 2 tails, and those among groups were assessed by analysis of variance followed by Bonferroni’s test. Statistical significance of changes in FPG, IRI, hemoglobin (Hb) A1c, HOMA-R, and washout rate by the treatments were assessed by analysis of variance for repeated measures. Simple least-sequences regression analysis was used to assess the correlation between 2 variables. A value of p<0.05 was regarded as significant.

Results
Baseline Characteristics (Table 1)
There were no significant differences in age, sex, heart rate, coronary risk factors other than DM, left ventricular mass index, and ejection fraction among the 3 groups, and no difference in body mass index, FPG, and HbA1c were recognized between the diabetic groups.

Changes in FPG, HbA1c, IRI, and HOMA-R
None of the patients were withdrawn during this study. The changes in FPG, HbA1c, and IRI are shown in Fig 2. Treatment with either troglitazone or glibenclamide for 3 months produced a similar reduction of FPG and HbA1c. IRI was not significantly but tended to be increased by glibenclamide, whereas it was decreased significantly by troglitazone. HOMA-R was also decreased significantly by troglitazone, but not by glibenclamide (Fig 3).

Washout Rate in ATP-Stress Thallium-201 Myocardial Scintigram
Baseline washout rates were 42±5% in controls, 30±4% in the troglitazone-treated group and 32±4% in the glibenclamide-treated group. The diabetic patient groups showed significantly lower washout rates than the control group. Heart rate, blood pressure, ejection fraction and serum creatinine were unchanged by the treatments in the diabetic groups. Fig 4 shows the washout rates before and 3 months after the drug treatments. In the troglitazone group, the washout rate was significantly improved, but not in the glibenclamide group. As shown in Fig 5, the increase in washout rate at the end-point of treatment from baseline correlated significantly with the decrease in HOMA-R.

Discussion
The present study demonstrated that troglitazone improved coronary circulation in the patients with NIDDM with insulin resistance and the improvement in washout rate correlated with a decrease of HOMA-R. Furthermore, glibenclamide did not improve the washout rate despite a similar reduction of FPG. This suggests that the beneficial effects of troglitazone on coronary circulation might be a result of improving insulin resistance rather than reducing the blood sugar level.

In the present diabetic patients, coronary microvascular disease may have been caused by hyperglycemia, as well as by hyperinsulinemia. Hyperglycemia induces advanced glycation end-products, activation of protein kinase C, and disturbance of the polyol metabolism pathway, resulting in oxidative stress in vascular vessel walls.27–29 The enhanced cellular oxidative stress reduces nitric oxide and activates nuclear factor-κb in endothelial cells30,31 which may stimulate proliferation of vascular smooth muscle cells and increase vasotonus, so-called vascular remodeling. The intensive management of hyperglycemia prevents the development and progression of cardiovascular complications in insulin-dependent DM in report of the DCCT study32 and Yokoyama et al also reported that blood glucose concentration rather than insulin resistance was the main cause of the reduced coronary flow reserve in NIDDM patients. However, in their study, treatment with sulfonylurea did not improve coronary circulation despite an adequate reduction in FPG and a decrease in HbA1c, for reasons that are unclear, although there are 2 possible causes. One cause might be the pharmacological action of sulfonylurea itself. Sulfonylurea, while promoting the release of insulin through a blockade of the metabolism-regulated ATP-sensitive potassium channels present in pancreas B-cell membranes, also blocks those
channels present in coronary vasculature, resulting in decreased nitric oxide in endothelium.37

Endogenous hyperinsulinemia inhibits constitutive nitric oxide synthase and increase free radicals through the activation of NADH/NADPH oxidase activity, resulting in decreased nitric oxide in endothelium. Thus, hyperinsulinemia might impair endothelium-dependent vasodilation and promote vascular remodeling.

Troglitazone is a newly developed antidiabetic agent that reduces insulin resistance. As confirmed in previous reports, troglitazone decreased blood sugar and plasma insulin level in the present study. In addition, troglitazone improved the washout rate in ATP-stress scintigraphy and the improvement correlated with a decrease in the plasma insulin level. This suggests that troglitazone might improve coronary microvessel disease by improving insulin resistance. Insulin promotes vascular hypertrophy and increases vascular tone, so troglitazone may restore coronary circulation through the improvement of vasomotor functions by reducing the plasma glucose level as well as the plasma insulin level. In conclusion, troglitazone may improve coronary circulation and prevent cardiovascular complication effectively in patients with NIDDM.
