A retrospective cohort study among tuberculosis patients registered in Shanghai TB Registry since 1972 was carried out during 1987–89 for testing the hypothesis on association of lung cancer with pulmonary tuberculosis. A total of 30,373 cases (male: 19,709 and female: 10,664) of pulmonary tuberculosis patients born before 1 January 1957 and resided in Shanghai urban were followed up until 1986. The SMRs for lung cancer were 1.38 and 2.73 in males and females, respectively, both of which were statistically significant. When the risk was adjusted by smoking, the adjusted SMRs for lung cancer were 1.72 (95% CI: 1.11–2.53) in males and 2.79 (95% CI: 1.79–4.14) in females. The elevated risk of lung cancer among tuberculosis patients was irrelevant to smoking. INH treatment and X-ray exposure can not be explained for this higher risk.

Pulmonary tuberculosis, Lung cancer, Cohort study, Smoking

INTRODUCTION

In a population-based case-control study on lung cancer in Shanghai urban involving interviews during 1984–86 with 1405 cancer patients and 1495 controls, a significant 50% elevation in the risk of lung cancer, adjusted for cigarette smoking, was observed among persons who had a history of tuberculosis¹. For testing the hypothesis on association of lung cancer with pulmonary tuberculosis generated by the case-control study, a retrospective cohort study among persons, who had a clinical manifestation of pulmonary tuberculosis, was carried out in Shanghai urban during 1987–89.

MATERIALS AND METHODS

The system of registration of tuberculosis patients in Shanghai area has been established since 1958 by the Shanghai Antituberculosis Network. Medical workers of the Network
periodically interview TB patients until recovery and fill in a unified card for each case with
general and medical information relevant to the patient including medical measures for
diagnosis and treatment such as intake of antituberculosis drugs, chest X-ray exposure, etc.
The registration cards kept by the Network were used for this study.

Since the completeness of registration and quality of keeping of registration cards during
late 1960s was seriously influenced by the special situation of that time, many cards filled in
before 1972 have been lost, so only the cards on cases of pulmonary tuberculosis registered
since 1972 were used in the study. During the period from 1 January 1972 to 31 December 1986
a total of 32,968 cases of pulmonary tuberculosis born before 1 January 1957 and resided in
Shanghai urban were registered and used as the cohort members.

The relevant information on each case was transcribed from card into an individual
questionnaire. Cases or relatives of the cases were interviewed at home by trained interviewers
for checking information obtained from cards and collecting information on smoking history
of the cases. Information on cause of death was also collected when case died. After coding the
data were input into the computer for processing and analyzing.

The standardized mortality ratio (SMR) with 95% confidence interval (CI) was used for
measuring association of lung cancer with pulmonary tuberculosis in the study. The age-
sex-specific mortality rates for lung cancer among general population in Shanghai urban
during three periods (1972–1976, 1977–1981, 1982–1986) were used as standard for
calculating SMRs. Trend test was used for the data grouped into more than two exposure
groups.

In order to avoid the bias stemmed from mistake in diagnosis of lung cancer of early stage
as pulmonary tuberculosis, all deaths occurred within three years after diagnosis of lung
tuberculosis as well as the observed person-years for first three years after diagnosis for all
cohort members were excluded in the analysis.

RESULTS

30,373 cases out of the total 32,968, which accounted for 92.1% of the total, were inter-
viewed. Among them there were 19,709 males and 10,664 females. Infiltration was the
predominant type of pulmonary tuberculosis at diagnosis, which accounted for 88.8% and
86.3% in males and females, respectively.

Table 1 presents SMRs with their 95% confidence intervals for all cancers and lung cancer
alone among persons who had a history of lung tuberculosis. The SMRs for lung cancer along
were 1.38 and 2.73 in males and females, respectively, both were statistically significant.
No significant SMR was observed for all cancers both in males and females.

In order to eliminate the effect of smoking on risk of lung cancer in the cohort, we calcu-
lated SMRs for lung cancer among nonsmoking cohort members at the age of 40 and over
among nonsmokers of general population in Shanghai urban during the period 1983-1986 as the
standard (Table 2). The rates in Table 2 are cited from a prospective cohort study involving
110 thousand adults resided in Shanghai urban and grouped as smokers and non-smokers(2).
The result showed that SMRs for lung cancer were 1.72 (95% CI: 1.11–2.53) in males and
2.79 (95% CI: 1.79–4.14) in females (Table 3), this implies that the elevated risk of lung
cancer among persons who had a history of pulmonary tuberculosis was irrelevant to smoking.

For elucidating the effect of intake of isoniazid on occurrence of lung cancer, SMRs for
lung cancer among cohort members were calculated by cumulative intake of isoniazid.

Higher SMRs were seen in all groups (Table 4), but by use of the trend test no statistically significant dose-response relationship between intake of isoniazid and occurrence of lung cancer was observed both in males and females. The result means that the higher risk of lung cancer can not be explained by use of the isoniazid. The similar result was also observed with regard to chest X-ray exposure (Table 5).
**DISCUSSION**

The possible relationship between pulmonary tuberculosis (TB) and the subsequent development of lung cancer has attracted attention for several decades. There have been numerous clinical reports of concurrent lung cancer with TB, and of cancers, especially adenocarcinoma and peripheral tumours, arising from TB scars\(^{(3,4)}\).

The results of epidemiologic studies were not the same. Most of them have suggested a moderate increase in the risk of lung cancer among TB patients \((1,5-10)\). The largest was a cohort study of 64,000 TB patients in Canada to evaluate the late effects of isoniazid\(^{(9)}\). A 1.5-fold excess risk of lung cancer was found in patients with TB as compared to the general population. Cohort studies in Australia\(^{(5,7)}\), Denmark\(^{(8)}\) and Israel\(^{(6)}\) revealed 2-fold or greater lung cancer risk among TB patients. 3 cohort studies in United States\(^{(11,13)}\) and United Kingdom\(^{(12)}\) have not found an increase risk of lung cancer, although the numbers of expected case were not large. Information on smoking for cohort members was available only in one out of 8 cohort studies, this Australian study\(^{(7)}\) has suggested that the excess risk was not confound by smoking. A case-control study in Hawaii revealed an 8-fold excess risk of lung cancer in nonsmoking women with a history of TB, but only 4 cases were affected\(^{(10)}\).

The recent population-based case-control study in Shanghai urban has found a 50% elevation in the risk of lung cancer adjusted for smoking among persons with a history of TB. The elevated risk was not related to the use of isoniazid. The effect of recent tuberculosis was most apparent for adenocarcinoma and peripheral tumours\(^{(1)}\).

The retrospective cohort study reported in this paper has confirmed the result of above-mentioned case-control study. In comparison to the general population a 38% and 173% elevation in the risk of lung cancer were observed in males and females with a history of TB. If only nonsmoking subjects were compared (non-smokers with a history of TB vs. non-
smokers of general population), the elevation in risk of lung cancer were 72% and 179% in males and females, respectively.

In the excess risk found in this study real? Firstly, as mentioned above, the effect of mistake in diagnosis of lung cancer as pulmonary tuberculosis was greatly reduced by means of exclusion of all deaths occurred within three years after diagnosis, since the 5 year survival rate for lung cancer was low, only 7% in Shanghai urban\(^\text{14}\). Secondly, according to health policy of the government, medical service is easily available for most of the residents of Shanghai urban, it is hardly to believe that more cases of lung cancer as cause of death were undetected in the general population. Thirdly, the effect of smoking on lung cancer has been removed in the study. By use of the age-sex-specific mortality rates of lung cancer for nonsmoking population as the standard, the elevation in risk of lung cancer in females almost remained unchanged, which can be explained by the very low prevalence of smoking among females\(^\text{15}\). In contrast with females the elevation in risk of lung cancer in males almost doubled, which probably has resulted from the high prevalence of smoking in general male population\(^\text{13}\) with higher mortality rates of lung cancer used as the standard. After removing the effect of smoking the relationship between lung cancer and TB was further clarified. In addition, in this study the relationship was not relevant to the duration of intake of isoniazid nor to the frequency of chest X-ray exposure, the same results as indicated in the previous case-control study\(^\text{1}\).

Despite diverse explanations the precise mechanisms of the relationship are still unclear. However, since both the case-control study and cohort study in Shanghai urban have given the similar result, it is rational to consider persons with a history of TB as a high risk group for lung cancer. After taking large-scale systematic preventive measures against tuberculosis which was very prevalent among residents in the past, tuberculosis now is not an important health problem in Shanghai. If the link between lung cancer and prior TB is a causal one, it was estimated from calculation of attributable risk that TB would account for less than 10% of the lung cancers today in Shanghai\(^\text{1}\).

ACKNOWLEDGEMENTS

The authors thank the staff of Shanghai Antituberculosis Network in urban districts for their contribution in data collection for the study.
