Cu²⁺ uptake by *A. nidulans* wild type was concentration dependent and followed Michaelis-Menten type kinetics with saturating concentration at 25 µM. A Lineweaver-Burk plot of the data revealed an apparent $K_m$ of 16.6 µM and a $V_{max}$ value of 2.5 nmol mg⁻¹ protein min⁻¹. No characteristic pH profile was evident for Cu²⁺ uptake in a pH range of 4.0–9.0, although the highest uptake rate was at pH 4.0. Uptake was sensitive to protonophore FCCP, suggesting the involvement of a proton gradient. Uptake was uninhibited in the dark or in the presence of DCCD, indicating that energy generated through ATP hydrolysis may not be directly involved in the uptake process. Genetic control of the transport was suggested on the ground that mutants differed among themselves as well as from the wild type in terms of $K_m$ and $V_{max}$ values.

Copper is an essential trace element required in various metabolic processes by microorganisms, algae and higher plants. But once the concentration of Cu²⁺, as in other heavy metals, reaches a critical level it becomes toxic to the cells. Previous studies on copper toxicity were mostly confined to growth, photosynthesis and nitrogen fixation (1, 2). Recently, copper has been shown to affect the uptake and assimilation of nitrate and ammonium (3, 4).

Copper uptake has been investigated in fresh water algae (5–7), marine diatoms (8), lichens (9) and plant cell cultures (10). It has been shown that algae are capable of accumulating Cu²⁺ to a considerable extent from the surrounding medium (11, 12) against the concentration gradient (13). Several workers have interpreted Cu²⁺ uptake in terms of a multiphasic isotherm (14–17) which may require the existence of a carrier, but which does not necessarily have to be active (18), whereas a biphasic model has been interpreted as an indication of an active process (19). However, two steps have to be understood during the Cu²⁺ uptake study: first, binding of ions on the cell surface and second, uptake of ions across the plasma membrane. So far little effort has been made to study the Cu²⁺ uptake in the cyanobacteria and photosynthetic microorganisms in general, and
no definite relation has been established between copper toxicity and uptake (20).

Keeping this information in view, an attempt has been made (a) to determine the Cu²⁺ uptake rate in the non-nitrogen fixing unicellular cyanobacterium *Anacystis nidulans* and (b) to study the Cu²⁺ transport under the framework of general criteria for transport systems.

**MATERIALS AND METHODS**

*Organism and growth condition.* Wild type *Anacystis nidulans* IU 625 (ATCC 27144) was obtained through the courtesy of Dr. R. S. Safferman, Cincinnati, Ohio, USA. The cultures were grown in HUGHES' medium (21), modified by ALLEN (22), supplemented with NaNO₃ (17.6 mM) and A₃ trace elements devoid of Cu⁺. The cultures were maintained in a culture room at a temperature of 24±1°C and illuminated for 14 hr per day by cool day-light fluorescent tubes (intensity approx. 250 ft. c. on the surface of the culture vessel).

*Isolation of mutants.* Wild type *A. nidulans* (2 x 10⁸ cells ml⁻¹) was exposed to Mn²⁺ (6 x 10⁻⁴ M) for 72 hr. The surviving cells (10⁶ cells ml⁻¹) were harvested and plated on medium supplemented with 0.5 mM NH₄⁺. Rapidly growing colonies were isolated and tested for resistance to the drug bacitracin. The mutants showing 2–3 fold resistance were selected and numbered *A. nidulans/Mn⁹*, *A. nidulans/Mn¹⁰* and *A. nidulans/Mn¹⁴*. They were grown in the medium as described for the wild type.

*Copper uptake experiments.* Exponentially growing cells were harvested and suspended in the buffer (0.01 M, pH 7.0) to a final density of 450 µg protein ml⁻¹. Uptake was initiated by adding Cu²⁺ (2.5 to 25 µM) in the form of CuSO₄·5H₂O (British Drug Houses, India) to account for the saturating level. The experiment was conducted in light (intensity approx. 250 ft. c.) at a temperature of 24±1°C. Samples were removed at regular intervals of 5–15 min, centrifuged (4,000 x g, 5 min) and analyzed for depletion with respect to time in the Cu²⁺ concentration in the supernatant. The linear portions of the curves were used to determine the uptake rate. The kinetic constants (*Kₘ* and *Vₘₐₓ*) were calculated from LINEWEAVER-BURK plots (23).

The pH of the assay medium was adjusted in the range of 4.0 to 9.0 with the following buffers: citrate phosphate buffer (pH 4.0–5.6), sodium phosphate (pH 6.0–7.6) and borate buffer (pH 8.0–9.0). The concentration of the buffer was adjusted to 0.01 M in each case.

*Non-specific binding of Cu²⁺.* To determine the non-specific binding of Cu²⁺ adsorbed on the cell surface, cells were suspended in 1.0 mM EDTA at room temperature for 15 min. The cells were separated by centrifugation (4,000 x g, 5 min) and the supernatant was analyzed for copper content.

*Inhibitors.* N,N'-dicyclohexylcarbodiimide (DCCD) and carboxylecyanide *p*-trifluoromethoxyphenyl hydrazone (FCCP) were obtained from Sigma.

...
Chemicals (USA). They were dissolved in ethanol in such a way that the final concentration of ethanol amounted to 0.01% in the assay medium. An inhibitor was added to the assay medium prior to the addition Cu$^{2+}$.

**Methods of measurement.** Growth was monitored by following changes in optical density ($\lambda=660$ nm). The specific growth rate was calculated by the equation of Kratz and Myers (24). Protein was estimated by the method of Folin-phenol (25) using lysozyme as the standard.

Copper concentration was measured colorimetrically as "carbamate" by the method of Jackson (26).

**RESULTS AND DISCUSSION**

*Effect of Cu$^{2+}$ on growth of wild type A. nidulans and mutants*

A comparison of growth of the wild type and mutants in graded concentration of Cu$^{2+}$ is shown in Fig. 1. The effect of Cu$^{2+}$ on growth has been represented in terms of percent increase or decrease in growth rate compared with the control. There was a differential effect of Cu$^{2+}$ on different strains. The 50% growth inhibitory concentration ($LD_{50}$) of Cu$^{2+}$ was 4 µM for the wild type, the most sensitive, strain. All the mutants showed resistance to Cu$^{2+}$ in comparison to the wild type: *A. nidulans*/Mn$^9$ was 1.25-fold more resistant ($LD_{50}=5.2$ µM Cu$^{2+}$), *A. nidulans*/Mn$^{10}$ was 2-fold more resistant ($LD_{50}=7.4$ µM Cu$^{2+}$) and *A. nidulans*/Mn$^{14}$ was 2.5-fold more resistant ($LD_{50}=10$ µM Cu$^{2+}$).

![Fig. 1. Effect of the graded concentration of Cu$^{2+}$ on the specific growth rate of *A. nidulans* wild type (○), *A. nidulans*/Mn$^9$ (●), *A. nidulans*/Mn$^{10}$ (●) and *A. nidulans*/Mn$^{14}$ (+). The results have been expressed as % increase or decrease in growth rate compared with the control (without Cu$^{2+}$).](image-url)
One of the characteristic features of *A. nidulans* /Mn	extsuperscript{0}, unlike other strains, was the apparent stimulation of growth compared with the control, at lower concentrations of Cu	extsuperscript{2+} (1–3 μM).

### Cu	extsuperscript{2+} uptake in wild type *A. nidulans*

The time course pattern of Cu	extsuperscript{2+} uptake showed that the uptake rate (1.26 nmol mg	extsuperscript{-1} protein min	extsuperscript{-1}) was a linear function of time for the first 15–20 min of incubation. During the next 15 min, the rate of uptake declined (0.86 nmol mg	extsuperscript{-1} protein min	extsuperscript{-1}). The uptake rates during the first 15 min of incubation were used in determining the kinetic constants (Fig. 2).

When uptake was studied in different concentrations of Cu	extsuperscript{2+} (2.5–25 μM), a Michaelis-Menten type of kinetics was observed with saturation in the uptake rate at 25 μM Cu	extsuperscript{2+} (data not shown). Thus, the uptake process apparently followed a monophasic isotherm in contrast to the multiphasic isotherm reported by Werff and Ernst (19). It is quite likely that a high affinity transport system might have been missed in the present investigation possibly due to the presence of a trace level contamination of Cu	extsuperscript{2+} in the constituents of the growth medium. This could be the reason for the apparent absence of growth stimulation by Cu	extsuperscript{2+} in the growth experiments. The Lineweaver-Burk plot of the uptake data revealed a $K_m$ of 16.6 μM and $V_{max}$ value of 2.5 nmol mg	extsuperscript{-1} protein min	extsuperscript{-1} (Fig. 4).

### pH profile and non specific binding of Cu	extsuperscript{2+} uptake

The Cu	extsuperscript{2+} uptake by *A. nidulans* wild type at different pH levels did not show a characteristic pH profile (Fig. 3). The uptake was maximal at pH 4.0, declined gradually up to pH 7.0, and remained constant between pH 8.0 to 9.0. The pH-

**Fig. 2.** Time course pattern of Cu	extsuperscript{2+} uptake by *A. nidulans* wild type. Cells harvested during the exponential phase were suspended in citrate-phosphate buffer (0.01 M, pH 4.2) and incubated in light at 24±1°C temperature. Uptake was initiated by the addition of 25 μM Cu	extsuperscript{2+}.
dependent Cu²⁺ uptake reflected the involvement of a net charge of ligands in which acidic pH favours the binding of cations. This is in conformity with earlier reports of the decrease of Cu²⁺ toxicity as the pH increases to alkaline range (27).

Since Cu²⁺ binds non-specifically to the cell surface, the extent of binding in the Cu²⁺-fed cells (for 15 min) at each pH was determined by washing the cells with EDTA (1.0 mM) and compared this with the total amount of Cu²⁺ uptake by cells (100%) at corresponding pH values. The results, presented in terms of the EDTA washable fraction as a percentage of the total Cu²⁺ uptake, showed the lowest non specific binding in the acidic range (i.e., 20% at pH 4.0). As the pH was increased, the EDTA washable fraction increased in a linear fashion and reached approximately 85% at pH 9.0 (Fig. 3). Thus, the highest rate of Cu²⁺ uptake was in the acidic range (pH 4.0). The increased toxicity of Cu²⁺ in the acidic range may be attributed to the increase in free Cu²⁺ ions available to the organism (28).
Table 1. Effect of metabolic inhibitors on Cu²⁺ uptake by wild type *A. nidulans*. Cells were suspended in phosphate buffer (pH 7.0, 0.01 M) and inhibitors were added 30 min prior to the addition of Cu²⁺ (25 μM).

Effect of inhibitors on copper uptake

To determine the possible source of energy for Cu²⁺ uptake, the effect of metabolic inhibitors on the uptake was investigated (Table 1). The copper uptake was uninhibited in the dark or in the presence of DCCD, an inhibitor of ATP-ase (29), indicating that light energy or energy generated through ATP hydrolysis may not be directly involved in the uptake process. On the other hand, a protonophore FCCP (30, 31) inhibited the Cu²⁺ uptake to a level of 55%. However, complete inhibition was not observed. This suggests that a proton gradient across the membrane may be governing the Cu²⁺ uptake.

Cu²⁺ uptake in mutants

Since the mutants differed in their sensitivity to Cu²⁺, it was interesting to investigate their relative uptake (Fig. 4). Lineweaver-Burk plots of the uptake data revealed that mutants differed from the wild type regarding affinity as well as uptake rate (Table 2). The mutant A. nidulans/Mn9 had a lower affinity (Kₘ = 25 µM) and a slower rate of uptake (Vₘₐₓ = 1.42 nmol mg⁻¹ protein min⁻¹) than the wild type. On the other hand, the affinity for Cu²⁺ was increased in mutants A. nidulans/Mn10 (Kₘ = 12.5 µM) and A. nidulans/Mn14 (Kₘ = 8.3 µM) with Vₘₐₓ values 2.5 and 1.6 nmol mg⁻¹ protein min⁻¹, respectively. The kinetic constants (Kₘ and Vₘₐₓ) of the mutants differed among themselves as well as from the wild type suggesting a genetic control of Cu²⁺ transport in A. nidulans.

I am thankful to the Head, Department of Botany, Banaras Hindu University, Varanasi-221 005, for providing me with the necessary facilities and financial assistance from the University Grants Commission.
