Objective: Obesity is a general risk factor for surgical site infection (SSI). In this study, we investigated the relationship between incisional SSI, which comprises two-thirds of the number of SSI cases, and measurements of subcutaneous fat thickness (SCF) instead of body mass index (BMI) as obesity index.

Materials and Methods: The subjects were 102 patients who underwent elective surgery of the lower digestive tract in our hospital from February 2004 to June 2005. The relationship between incisional SSI and the following parameters was investigated: sex, age, obesity (SCF), BMI, anemia, nutritional condition, respiratory function (preoperative PaO₂), preoperative systemic condition, incidence/absence of diabetes, operation time, bleeding volume and procedure type.

Results: The odds-ratio and p-values were 5.873 and 0.011 in the high-SCF group and 4.997 and 0.019 in the low-preoperative PaO₂ group, respectively.

Conclusions: It was suggested that the high-SCF and low-preoperative PaO₂ groups were high-risk groups for incisional SSI.

Key Words: surgical site infection, incisional surgical site infection, surgery of the lower digestive tract

Introduction

Postoperative surgical site infection (SSI) is the most common postoperative complication after surgery of the digestive tract. In particular, following surgery of the lower digestive tract, the incidence of complications is very high and SSI risk factors and measures are important issues for surgeons for the lower digestive tract.

Obesity is one of the risk factors for SSI and subcutaneous fat at the actual infected site is also an important factor. In this study, we investigated the relationship between incisional SSI which is one of the classification of SSI (Fig. 1) and multiple factors including measurements of subcutaneous fat thickness (SCF) in patients who underwent elective surgery of the lower digestive tract.

Materials and Methods

The subjects were 102 patients who underwent elective surgery of the lower digestive tract in our hospital from February 2004 to June 2005. In this study, steroid-treated and hemodialyzed patients were excluded. The subjects consisted of 63 male and 39 female patients of 39–86 years old (mean age: 65.5±10.8 years old).

Based on the diagnostic criteria of the Cen-
ters for Disease Control and Prevention in the United State (CDC)\(^3\), the presence/absence of incisional SSI was evaluated and 22 patients were diagnosed with SSI (SSI (+) group) and 80 patients without SSI (SSI (-) group).

**Evaluation items**

1. **Patient factors**

1. **Sex**
2. **Age**

The patients were classified into low and high-age groups with a cut-off of 66 years old.
3. **Obesity**
   a) **SCF**
   
   Subcutaneous fat thickness (mm) at the midline point just above the umbilicus was measured in abdominal CT scan before surgery. The patients were classified into low and high-SCF groups with a cut-off value of 18 mm.
   b) **Body Mass Index (BMI)**

The patients were classified into high and low-BMI groups above and below 25 based on the diagnostic criteria of the Japan Society for the Study of Obesity\(^4\).
4. **Anemia**

Anemia was diagnosed with preoperative hemoglobin based on the diagnostic criteria of

* American Society of Anesthesiologist ** Physical Status
our hospital (male: 13.4 g/dl; female: 11.1 g/dl).

5. Nutritional condition
Nutritional condition was determined with preoperative albumin based on the diagnostic criteria of our hospital and patients were classified into two groups (above or below 4.0 g/dL).

6. Respiratory function
Respiratory function was diagnosed with preoperative PaO2 and the patients were classified into two groups with a cut-off value of 86 mmHg.

7. Preoperative systemic condition
Preoperative systemic condition was diagnosed in accordance with the criteria for physical status of the American Society of Anesthesiologists (ASA) and the patients were classified into two groups (No-risk group: 2 and less, Risk group: 3 and more) based on the Risk Index for SSI National Nosocomial Infections Surveillance (NNIS) of the CDC (Table 1).

8. Diabetes
Patients who were being treated for diabetes and patients whose fasting blood glucose level was 110 mg/dl and higher on admission were considered diabetic patients.

II. Surgical factors
1. Operation time
The patients were classified into two groups with a limit of 180 minutes, which was defined as "risky" on colon surgery by the NNIS.

2. Bleeding volume
The patients were classified into two groups according to whether or not they lost a volume of 200 ml of blood intraoperatively.

3. Procedure type
Procedure types were classified based on the Japanese Classification of Colorectal Carcinoma (6th edition). The breakdown of procedure types was as follows: 44 cases of anterior resection; 8 cases of abdominoperineal resection; 14 cases of sigmoidectomy; 3 cases of left hemicolectomy; 22 cases of right hemicolectomy; 3 cases of ileocecal resection; 7 cases of subtotal colectomy and 1 case of total colectomy. All cases underwent open laparotomy.

<td></td>
</tr>
</tbody>
</table>
As for the patient factors of age, SCF and PaO₂ and surgical factor of bleeding volume, the patients were classified into two groups to show the minimum differences in the number of patients between the groups.

Surgical wounds of all patients were classified into Class II (clean-contaminated) based on the classification for surgical wounds in SSI Surveillance by the CDC⁸⁻⁹ (Table 2).

Statistical analyses were conducted using SPSS II for Windows Version 11.0J (SPSS Inc.). χ² test was used for univariate analysis (significance test between 2 groups) and logistic regression analysis was used for multivariate analysis (significance test for multigroup comparison). The significance level was considered to be 0.05.

**Results**

1. **Univariate analysis**

   I. **Patient factors (Table 3)**

   1) **Sex**

      The SSI (+) group comprised 12 males (54.5%) and 10 females (45.5%) and the SSI (−) group consisted of 51 males (63.8%) and 29 females (36.2%), suggesting no significant differences between the groups.

   2) **Age**

      In the group aged less than 66 years, there were 10 patients (45.5%) in the SSI (+) group
Study of Factors for Incisional Surgical Site Infection after Elective Surgery of the Lower Digestive Tract

and 40 patients (50.0%) in the SSI (−) group. In the group aged 66 years and more, there were 12 patients (54.5%) in the SSI (+) group and 40 patients (50.0%) in the SSI (−) group. No significant differences in SSI were found between the groups by age.

3) Obesity

a) SCF

In the group with SCF less than 18 mm, there were 6 patients (27.3%) in the SSI (+) group and 47 patients (58.8%) in the SSI (−) group. In the group with SCF of 18 mm or more, there were 16 patients (72.7%) in the SSI (+) group and 33 patients (41.2%) in the SSI (−) group. The incidence of SSI was significantly higher in the group with SCF of 18 mm or more (p = 0.009).

b) BMI

In the group with a BMI of less than 25, there were 13 patients (59.1%) in the SSI (+) group and 63 patients (78.8%) in the SSI (−) group. In the group with a BMI of 25 or more, there were 9 patients (40.9%) in the SSI (+) group and 17 patients (21.2%) in SSI (−) group. The incidence of SSI was higher in the group with a BMI of 25 or more without any significant difference (p = 0.061).

4) Anemia

In the group with anemia (male : 13.4 g/dl and lower; female : 11.1 g/dl and lower), there were 14 patients (63.6%) in the SSI (+) group and 39 patients (48.7%) in the SSI (−) group. In the group without anemia, there were 8 patients (36.4%) in the SSI (+) group and 41 patients (51.3%) in the SSI (−) group. No significant differences in the incidence of SSI were between the groups by anemia.

5) Nutritional condition

In the group with albumin levels of less than 4.0 g/dl, there were 16 patients (72.7%) in the SSI (+) group and 46 patients (57.5%) in the SSI (−) group. In the group with albumin of 4.0 g/dl and higher, there were 6 patients (27.3%) in the SSI (+) group and 34 patients (42.5%) in the SSI (−) group. No significant differences in the incidence of SSI were found between the groups by nutritional condition.

6) Respiratory function.

In the group with preoperative PaO$_2$ of less than 86 mmHg, there were 16 patients (72.7%) in the SSI (+) group and 34 patients (42.5%) in the SSI (−) group. In the group with preoperative PaO$_2$ of 86 mmHg and higher, there were 6 patients (27.3%) in the SSI (+) group and 46 patients (57.5%) in the SSI (−) group. The incidence of SSI was significantly higher in the group with preoperative PaO$_2$ of less than 86 mmHg (p = 0.012).

7) ASA physical status

In the group with ASA physical status of less than 2, there were 21 patients (95.5%) in the SSI (+) group and 74 patients (92.5%) in the SSI (−) group. In the group with ASA physical status of 3 and higher, there was 1 patient (4.5%) in the SSI (+) group and 6 patients (7.5%) in the SSI (−) group. No significant differences in the incidence of SSI were found between the groups by ASA physical status.

8) Diabetes

In the non-diabetic group, there were 18 patients (81.8%) in the SSI (+) and 70 patients (87.5%) in the SSI (−) group. In the diabetic group, there were 4 patients (18.2%) in the SSI (+) group and 10 patients (12.5%) in the SSI (−) group. No significant differences in the incidence of SSI were found between the groups according to diabetes.

II. Surgical factors (Table 4)

1) Operation time

In the group with an operation time of less than 180 minutes, there were 7 patients (31.8%) in the SSI (+) group and 34 patients (42.5%) in the SSI (−) group. In the group with an operation time of 180 minutes and longer, there were
15 patients (68.2%) in the SSI (+) group and 46 patients (57.5%) in the SSI (-) group. No significant differences in the incidence of SSI were found between the groups by operation time.

2) Bleeding volume

In the group with a bleeding volume less than 200 ml, there were 10 patients (45.5%) in the SSI (+) group and 44 patients (55.0%) in the SSI (-) group. In the group with a bleeding volume of 200 ml and more, there were 12 patients (55.5%) in the SSI (+) group and 36 patients (45.0%) in the SSI (-) group. No significant differences in the incidence of SSI were found between the groups by bleeding volume.

3) Procedure type

In the anterior resection group, 6 (27.3%) of 44 patients were in the SSI (+) group, and in the abdominoperineal resection group, 4 (18.2%) of 8 patients were in the SSI (+) group. In the sigmoidectomy group, 3 (13.6%) of 14 patients were in the SSI (+) group. In the left hemicolectomy group, 2 (9.1%) of 3 patients were in the SSI (+) group, and in the right hemicolectomy group, 4 (18.2%) of 22 patients were SSI (+). In the ileocecal resection, 1 (4.5%) of 3 patients was in the SSI (+) group, and in the subtotal colectomy group 2 (9.1%) of 7 patients were in the SSI (+) group. None of the patients (0%) who underwent total colectomy were in the SSI (+) group. No significant differences in the incidence of SSI were found between the groups by procedure type.

2. Multivariate analysis (Table 5)

All items that underwent univariate analysis were also evaluated with the multivariate analysis.

Of patient factors, the odds-ratio, 95% confidence interval and p-values were 5.873, 1.498–23.030 and 0.011 in the high-SCF group and 4.997 1.301–19.197 and 0.019 in the low-preoperative PaO2 group, respectively. Therefore, high-SCF and low-preoperative PaO2 were selected as risk factors increasing the incidence of incisional SSI.

Discussion

SSI comprises the third highest (14% to 16%) hospital infectious disease and 38% of hospital infectious diseases in patients who underwent surgery. In particular, incisional SSI comprises two-thirds of total SSI and its development increases medical expenses and prolongs hospitalization periods, which causes physical and mental strain on patients. Therefore, if the factors that contribute to the

* Subcutaneous fat ** Body Mass Index *** American Society of Anesthesiologist
onset of incisional SSI and clarified, reduction of the incidence of SSI and medical expenses could be helpful for patients.

The NNIS system indicated SSI risk factors, i.e., (1) duration of surgery more than the limited hours (180 minutes in colon surgery); (2) 3 and higher ASA physical status score, and (3) Class 3 or 4 (contaminated or infected) operation. In this study, no significant differences in the incidence of SSI were found between the groups according to operation time and ASA physical status. Nishioka et al. reported no significant differences in the incidence of SSI between the groups according to operation time and ASA physical status, and the validity of the NNIS SSI risk factors has not been confirmed in Japan. In this study, no significant differences in the incidence of SSI were shown between the groups by sex, age, anemia, nutritional condition and diabetes (patient factors) and bleeding volume and procedure type (surgical factors). The CDC Guideline (1999) indicated that age, nutritional condition, diabetes and operation time were risk factors for SSI. Some studies reported that significant differences in the incidence of SSI were found between the groups based upon anemia, procedure type and bleeding volume. In this study, the incidence of SSI was high in the high-BMI group, however, no significant differences were found. In studies in Europe and the United States, the incidence of SSI was significantly high in the high-BMI group. This discrepancy was related to the difference in obesity rate, i.e., in Europe and the United States, 30% of people had a BMI 30 or more but this proportion only comprised approximately 3% of the Japanese subjects. As for SCF which was an index for obesity used in this study in addition to BMI, surgeons know empirically that incisional SSI develops frequently in patients with high SCF. However, few studies have confirmed the relationship between SCF and the incidence of incisional SSI. The results of this study showed significant difference between SCF and the incidence of incisional SSI. BMI has been adopted as an index for obesity in most countries. However, in East Asia including Japan and Southeast Asia where there are few obese people with a BMI of 30 or more, SCF has been considered more useful as a risk factor for the incidence of incisional SSI compared with BMI.

Inadequate oxygenation of the hypodermal tissue was one of the reasons for the high incidence of incisional SSI in the high-SCF group. Barbara et al. reported that wounds and tissues of obese patients were hypoxic and that insufficient oxygenation in the hypodermal tissue increased portoperative infection in obese patients.

The results of our study also demonstrated a significantly high incidence of incisional SSI in the low preoperative PaO2 group, which suggested that respiratory dysfunction inhibited oxygenation in tissues during and after surgery, leading to infection.

The incidence of incisional SSI in the United States ranged from 3% to 30% (mean: approximately 10%) However, the incidence in this study was 21.6%, slightly higher. One possible reason is that the admission period in the United States is shorter than that in Japan and surveillance after discharge were not conducted for a sufficiently long duration.

SSI has an adverse effect on patients and is an important problem for surgeons. Therefore, in accordance with the NNIS, the Japanese Society of Environmental Infections devised the nosocomial infection surveillance system in Japan in 1998 and has been conducting surveillance of SSI. It was reported that introduction of this system reduced the incidence of SSI.
Various devices and procedures have been developed to reduce the incidence of incisional SSI as follows: use of protection for wounds and its surrounding including a wound protector\(^{27}\) and bandage protector\(^{28}\), lavage of the hypodermal tissue immediately before closure of the skin using warm saline and sterilized sponge\(^{29}\), insertion of a Penrose drain and an aspiration drain into the hypodermal tissue\(^{29}\).

Considering our results, the high-SCF and low-preoperative PaO\(_2\) patients were considered a high-risk group for incisional SSI, and the above preventive procedures would be effective for reduction of the incidence of incisional SSI.

**Conclusion**

It was suggested that the incidence of incisional SSI was higher in patients with thick subcutaneous fat.

It was suggested that the incidence of incisional SSI was higher in patients with low-preoperative PaO\(_2\).
