Abstract: To clarify the effects of cold acclimation and immobilization stress adaptation of rats on nitric oxide (NO) activity in interscapular brown adipose tissue (BAT), we incubated neatly diced (1-mm³ blocks) BAT in a metabolic chamber for respiration, measured oxygen consumption using a Clark electrode, and estimated NO release in the buffer medium by measuring nitrite plus nitrate (NOₓ) using the Griess method (diazotization reaction). The production of NOₓ in the buffer medium confirmed that BAT releases NO, as there is no other source of NOₓ in the system.

Key words: brown adipose tissue, nitric oxide, in vitro oxygen consumption, nonshivering thermogenesis.

Brown adipose tissue (BAT) is a thermogenic organ and its thermogenesis is indispensable when nonshivering thermogenesis is the main source of heat for body temperature regulation in mammals. Exposure of animals to a cold ambient temperature activates BAT, enhancing nonshivering thermogenesis to maintain a constant body temperature. Daily immobilization stress for several hours over several weeks in rats also activates the BAT function, and when these animals are exposed to a cold ambient temperature, they show an enhanced nonshivering thermogenic capacity, a phenomenon which is termed as cross adaptation [1–4]. Both cold exposure and repetitive immobilization stress may stimulate the sympathetic nervous system, initiating BAT activities responsible for the enhancement of nonshivering thermogenesis.

Blood flow perfusing BAT determines the thermogenic activity of the tissue. When the rats are exposed to cold or injected with noradrenaline, the tissue is perfused with more blood to meet the increased metabolic demand. This increase in BAT blood flow ceases if the rats are co-injected with Nω-nitro-L-arginine methyl ester (L-NAME; a nitric oxide synthase inhibitor), implying a role for nitric oxide (NO) in the regulation of BAT blood flow [5]. This finding justified further investigation to explore the role of NO in BAT nonshivering thermogenesis. Subsequently, we reported that chronic treatment with L-NAME decreases the nonshivering thermogenic capacity of rats. The L-NAME–treated rats develop hypothermia on acute exposure to a cold ambient temperature and do not show any response to noradrenaline that normally increases oxygen consumption in vivo [6]. The thermogenic capacity of BAT isolated from these rats, as estimated by DNA content and in vitro oxygen consumption, is also found to be suppressed. In these previous studies, we adopted pharmacological means to suppress the NO synthase, but did not show any firm evidence of NO synthesis in BAT. In addition, it is not known if the physiological conditions that are known to enhance adaptive thermogenesis would enhance the capacity for NO synthesis in BAT. In this study, therefore, we addressed the question of firm evidence of NO in BAT.
and the effects of cold acclimation and repetitive immobilization stress adaptation on NO in BAT in relation to the thermogenic capacity of BAT.

MATERIALS AND METHODS

Animals. Male Wistar rats were used in the experiments. They were obtained from Shizuoka Laboratory Animal Center, Hamamatsu, Japan. The rats were 7 weeks old when they were purchased and were kept in our animal laboratory for 1 week before grouping them for the experiments. They were housed in wire cages (three to five per cage) with free access to food (laboratory rat biscuits; Oriental MF, Oriental Yeast Co., Ltd., Tokyo, Japan) and tap water. Seven rats were housed in a cold room for 5 weeks for cold acclimation (CA). The temperature of the cold room was maintained at 5±1°C. Another group of seven rats were housed in a warm room (25±1°C, 50% relative humidity) and subjected to 3 h-immobilization stress every day for 5 weeks using a wooden board and wire mesh for immobilization stress adaptation (ISA) (1). A group of 12 rats that were the control for the CA and ISA experiments were housed in the warm room. The rats were sacrificed by decapitation and the interscapular BAT was taken out, carefully separated from other tissues (such as muscles, large blood vessels, white adipose tissue) and the wet weight of the tissue was measured. The experimental protocol was approved by the Institutional Animal Care and Use Committee and complies with the laws of Japan.

In vitro oxygen consumption. BAT was carefully diced (ca. 1-mm³ blocks) and kept in a plastic vial containing 8 ml of air-saturated Krebs-Ringer phosphate buffer (pH 7.4) at 37°C under slow shaking. The buffer contained the following (mmol/l): 120 NaCl, 4.8 KCl, 1.3 CaCl₂, 1.2 MgSO₄, 3 NaH₂PO₄, and 12.7 Na₂HPO₄. The buffer also contained glucose at 5 mmol/l and 4% bovine serum albumin (Armour Co., Fraction V, dialyzed for 48 h through cellulose membrane against Krebs-Ringer phosphate buffer, pH 7.4, to remove fatty acids). After two to three hours, a portion of the tissue (about 25 mg) was transferred to a magnetically stirred metabolic chamber containing 2 ml of the same air-saturated buffer for measurement of oxygen consumption. In the case of oxygen consumption of tissue slices, results with phosphate buffer were reported not to differ significantly from those with bicarbonate buffer [7]. In the case of the BAT blocks we used in this study, these two buffers were found not to differ significantly (unpublished observation). The chamber was closed, and oxygen consumption was measured by a Clark electrode (Rank Brothers, Cambridge, UK). The basal oxygen consumption was measured for 5 min. After this, noradrenaline [(−)-Arterenol bitartrate salt (Sigma)] was added with a Hamilton syringe through a small hole in the cover of the chamber. The concentration of noradrenaline in the chamber was 6 μM, and this concentration has been shown to produce maximal stimulation of BAT from 25°C-acclimated rats [8]. The rate of oxygen consumption of the electrode itself in the presence of 2 ml buffer over a period of 10 min was measured routinely before the tissue blocks were added. The buffer initially contained 217 nmol O₂/ml.

Nitrite and nitrate assay. Diced BAT was incubated for 50 min in the metabolic chamber with or without noradrenaline in the medium as described above. Then, the medium was collected for nitrite assay using NO₂/NO₃ assay kit-C (Dojindo Laboratories, Japan). This assay method is based on a diazotization reaction producing azo compounds from sulfanilamide with nitrite and 1-naphthylethylenediamine. The absorbance of the coloured azo compound was measured at the wavelength of 540 nm by use of a microplate reader. Nitrate was first converted to nitrite enzymatically before assay. The nitrate reductase and enzyme co-factor are included in the kit. Figure 1 shows a representative nitrite standard reference curve for the same buffer medium we used in the experiments. NO production in the buffer medium was estimated by measuring nitrite and nitrate as they are stable and non-volatile breakdown products of NO.

Data analysis. Data were expressed as the mean±SE. The significance of differences between the groups was analyzed using analysis of variance (ANOVA) followed by Scheffe’s F-test, Fisher’s protected least-significant difference test or the Mann
Whitney U-test when suitable. When linear regression analysis was performed, Student’s t-test was used to determine whether the mean slope deviated significantly from 0. We considered differences significant at $p<0.05$.

RESULTS

Body weight and BAT weight

Rats were divided into three groups by matching their body weights. The increase in body weight was smaller in the CA and ISA groups than in the control group (Table 1). The BAT weight was larger in the CA and ISA groups than in the control group (Table 1). These results reflected cold acclimation and immobilization stress adaptation [1, 9]. Agreeing with previous reports [1, 9], the BAT weight in the CA group was larger than that in the ISA group.

In vitro oxygen consumption

The results of in vitro oxygen consumption are summarized in Fig. 2. The basal in vitro oxygen consumption as expressed per milligram of BAT was larger in the ISA group than in the control group (Fig. 2A). The basal in vitro oxygen consumption in the CA group was not significantly different from the control group. Administration of noradrenaline increased the oxygen consumption of BAT from the basal levels in the control and ISA groups. Noradrenaline administration did not significantly change the oxygen consumption from the basal level in the CA group. The oxygen tension in the chamber declined over time. Figure 2B shows the decline in oxygen tension in $\mu$mol l$^{-1}$ (mean of the lowest to mean of the highest at the indicated time-range) while measuring oxygen consumption in the control rats. The noradrenaline-stimulated maximum oxygen consumption was recorded at 5–10 min at an oxygen tension of 127–166 $\mu$M in the control group. After that, the rate of oxygen consumption declined to near the basal level. The final oxygen tension in the chamber was 75–97 $\mu$M (Fig. 2B). As the total oxygen consumption in the ISA was larger, the oxygen tension in the chamber declined from the initial 217 $\mu$M to a final 34 $\mu$M (not shown). As the total oxygen consumption in the CA was smaller, the oxygen tension in the chamber declined from the initial 217 $\mu$M to a final 146 $\mu$M (not shown).

Nitrite and nitrate

The results of the nitrite and nitrate assay are shown in Fig. 3. The basal production of nitrite plus nitrate (NO$_x$) as expressed per milligram of BAT was larger in the CA (3.0±0.33 pmol/mg/min, $p<0.01$) and ISA (3.5±0.66 pmol/mg/min, $p<0.001$) groups than in the control group (1.2±0.19 pmol/mg/min). Administration of noradrenaline increased the production of NO$_x$ from the basal level in the control group. Noradrenaline administration did not significantly change the

production of NO\textsubscript{x} from the basal levels in the CA and ISA groups. The noradrenaline-stimulated NO\textsubscript{x} levels were larger in the CA (3.1 ± 0.36 pmol/mg/min, \( p < 0.05 \)) and ISA (4.0 ± 0.44 pmol/mg/min, \( p < 0.001 \)) groups than in the control group (2.2 ± 0.20 pmol/mg/min).

Regression analysis

Administration of noradrenaline increased the NO\textsubscript{x} production and oxygen consumption of BAT from the basal level in the control group. A regression analysis showed a correlation between NO\textsubscript{x} and oxygen consumption (Fig. 4A). The basal level of NO\textsubscript{x} and the basal level of oxygen consumption were larger in the ISA group than in the control group. Another regression analysis showed a correlation between basal NO\textsubscript{x} and basal oxygen consumption in these groups (Fig. 4B). The basal level of NO\textsubscript{x} was larger in the CA group than in the control group, but did not correlate with oxygen consumption (not shown).

DISCUSSION

We demonstrated here that small tissue blocks of freshly collected BAT from rats produced NO\textsubscript{x} when they were incubated in a metabolic chamber for in vitro assay of oxygen consumption. This is firm evidence of NO activity in BAT, as there is no other source of NO\textsubscript{x} in the incubation medium. This also confirms previous findings suggesting that BAT produces NO [6, 10–13]. Furthermore, this study showed that cold acclimation and repetitive immobilization stress, which are known to enhance the thermogenic capacity of BAT [1, 3], enhanced the production of NO\textsubscript{x} in the basal condition. Noradrenaline stimulation caused an increase in NO\textsubscript{x} production in warm-acclimated control rats. These findings indicate that NO may be involved in enhancement of the thermogenic function of BAT in rats.

It is known that chronic exposure of rats to a cold ambient temperature or to repetitive immobilization stress discharges sympathetic signals to BAT, activating the tissue for nonshivering thermogenesis. The control rats are considered to have less active BAT. The elevated basal level of NO\textsubscript{x} in the ISA and the noradrenaline-stimulated level in the control rats correlated with in vitro oxygen consumption (Fig. 4). These results suggest that NO is active in BAT as a signal molecule and enhances the thermogenic capacity of BAT. It is, however, observed that noradrenaline increased in vitro oxygen consumption from the basal level significantly, but not NO\textsubscript{x} production in the ISA...
group. The exact cause of the disparity is not clear in this study. Noradrenaline administration did not increase NO production from the basal level in the CA group either.

The in vitro oxygen consumption as expressed per milligram of BAT was elevated in the ISA group in comparison with the control rats (Fig. 2) as previously reported [3]. In contrast, in vitro oxygen consumption was not elevated in the CA group as previously reported [2], although BAT in the CA group undoubtedly had elevated activity and capacity for nonshivering thermogenesis [2]. The capacity of BAT for nonshivering thermogenesis is a function of the number of brown adipocytes, the number of mitochondria in adipocytes, their mitochondrial protein content, and the concentration of uncoupling protein in the mitochondria. The CA rats show elevated levels of these parameters [14]. NO is involved in the regulation of BAT thermogenesis. It is therefore suggested that a NO-cGMP pathway is involved due to acute cold exposure or cold-acclimation [14, 23, 24]. It has been suggested that cytochrome oxidase has evolved from the enzymes of anaerobic respiration [25, 26]. Brown adipocyte mitochondria have cytochrome oxidase at the terminal site of the respiratory chain. As an alternative substrate for cytochrome c oxidase, NO functions as an electron acceptor in the respiratory chain. This inhibition is reversible and depends on oxygen tension and NO concentration. The lower the oxygen tension is, the higher the inhibitory action of NO. Although we measured the respiration of BAT cells in this study, it is necessary to evaluate whether there is any possibility of NO influencing in vitro oxygen consumption by binding with cytochrome c oxidase. In this study, about 25 mg of BAT suspended in 2 ml of buffer was incubated in the metabolic chamber for oxygen consumption. We calculated that the maximum accumulation of NO per minute in the metabolic chamber ranges from 28 to 50 nM, which is derived from 28 to 50 nM NO. As NO has a very short half life of less than 1 min, and if we consider that it takes about 2 min for the total disappearance of NO once produced, the level of NO in the chamber will be a little more than this value. This concentration of NO may inhibit oxygen consumption at a very low oxygen tension [17, 18, 22]. But, for half-inhibition of respiration at an oxygen tension of around 200 μM (near the oxygen tension in the 1st half of noradrenaline stimulation in our experiment), the NO concentration in the chamber should be more than 8 times higher as reported in the experiments of mitochondrial preparation [18]. In agreement with this observation, we found that noradrenaline stimulation increased oxygen consumption (respiration) during the first 10 min and reached a peak, implying that NO-mediated inhibition of respiration was not predominant at this phase. As oxygen was being consumed in the closed system, the oxygen tension in the system declined during this time, increasing the possibility that NO functions as an inhibitor of mitochondrial respiration. This may be the cause for the rapid decline of oxygen consumption by BAT after reaching the peak, otherwise the peak should have plateaued as the incubation medium still contained noradrenaline (Fig. 2B).

On the other hand, in vitro oxygen consumption of BAT in the CA group was smaller than that in the other two groups and did not respond to noradrenaline. However, as mentioned earlier, this result cannot be reconciled with the fact that cold-acclimation enhances the thermogenic activity and capacity of BAT. The mitochondria of brown adipocytes are mainly coupled in warm-acclimated rats, but become uncoupled due to acute cold exposure or cold-acclimation enhancing the thermogenic capacity [14, 23, 24]. It has been suggested that cytochrome oxidase has evolved from the enzymes of anaerobic respiration [25, 26]. Brown adipocyte mitochondria have cytochrome oxidase at the terminal site of the respiratory chain. As an alternative substrate for cytochrome c oxidase, NO functions as an electron acceptor instead of O₂, producing N₂O and H₂O [20, 21]. This may bypass the detection of NO release by measuring NOₓ. We found no change in the NOₓ production with noradrenaline stimulation in the CA group. If this al-
alternative substrate reaction (NO instead of O$_2$) produces heat in BAT, the enigma that BAT produces heat \textit{in vitro} but consumes less oxygen would be explained.

We conclude that BAT produces NO and enhanced NO activity is related to the enhanced activity and capacity of BAT for nonshivering heat production in rats.
