ROLE OF ADRENERGIC RECEPTORS IN THE CENTRAL THERMOREGULATORY MECHANISM OF THE RAT

Abstract Changes in rectal and skin temperatures following intraventricular injection of norepinephrine and receptor specificity of the response in the rat were investigated. Intraventricular injection of norepinephrine in a small dose (6 μg) produced a slight elevation in rectal temperature, but in larger amounts (25–50 μg) the result was a dose-dependent hypothermia associated with a marked rise in skin temperature. No change was observed in oxygen consumption after intraventricular injection of norepinephrine (25 μg). Intraventricular injection of phenoxybenzamine prior to norepinephrine blocked hypothermia and skin temperature elevation which are normally observed following norepinephrine injection, while propranolol given in the same way showed less or no effect. Intraventricular injection of phenylephrine produced a dose-dependent hypothermia, whereas a no dose-response relationship was obtained with isoproterenol. These results suggest that in the rat the hypothermic effect of norepinephrine injected intraventricularly is mediated by the action of central alpha receptors.

The concept that body temperature is regulated by a fine balance in the release of catecholamines and 5-hydroxytryptamine in the anterior hypothalamus was first proposed by Feldberg and Myers (1963, 1964, 1965) who studied changes in body temperature following central administration of these amines in unanesthetized cats. Many subsequent investigators have revealed considerable species differences in the direction and magnitude of rectal temperature changes. In the rat, intraventricular injection of a small dose (2–6 μg) of norepinephrine produced an increase in rectal temperature preceded by a brief fall (Feldberg and Lotti, 1967; Bruinvels, 1970), whereas larger doses (10–50 μg) of the amine have been reported to elicit either hypothermia (Feldberg and Lotti, 1967;...
Thus, the primary effect of centrally applied norepinephrine in the rat is not clear.

The existence of central adrenergic receptors has been demonstrated, but they may not be necessarily related to their known actions on peripheral receptors. There is evidence to indicate that the hypothermia elicited by norepinephrine injected into the hypothalamus or the lateral ventricle of the mouse (Brittain and Handley, 1967), cat (Burks, 1972; Rudy and Wolf, 1971) and golden hamster (Reigle and Wolf, 1974) may be due to action on central receptors of the alpha type. In the rat, however, the role of adrenergic receptors on central thermoregulation has not been shown. Accordingly, the present experiments were undertaken to investigate the dose-dependent characteristics and receptor specificity of the central thermoregulation induced by injection of norepinephrine into the lateral ventricle of the rat.

MATERIALS AND METHODS

Male albino rats of the Wistar strain, weighing from 250 to 350 g, were used for all experiments. They were housed in an air-conditioned (23±2°C) and light-controlled (lights on from 6:30 am to 6:30 pm) room and allowed access to food (Oriental MF) and water ad libitum.

Animals were anesthetized with sodium pentobarbital (50 mg/kg i.p.) and a No. 5 polyethylene tube cannula with an outer diameter of 0.8 mm and a length of 2 cm was implanted aseptically into the right lateral ventricle utilizing a stereotaxic technique. The cannula was placed 2.5 mm lateral to the sagittal suture and 1 mm posterior to the coronal suture and opening of the cannula tip was 4 mm below the skull surface. The cannula was permanently affixed to the skull with dental cement. After surgery the animals were housed in individual cages and given antibiotics parenterally for 5 days. After a week, the animals recovered and were gentled by daily manual handling. One day before the experiment, 7.5 μl isotonic saline was injected into the ventricle through the implanted cannula. In order to verify the cannula placement, at the end of experiment 7.5 μl methylene blue was injected through the cannula and the dye that spread in the ventricular systems was examined macroscopically.

Rectal temperature at a depth of 5 cm from the anus and the skin temperature of the tail were measured by using a thermister at 10 min intervals before and after intraventricular injection of drugs. Heat production was estimated from the rate of oxygen consumption employing an closed-circuit spirometer by Collins.

All drugs were dissolved in 0.9% sodium chloride solution just prior to use. 7.5 μl of the drug solution was injected by microsyringe through the cannula into the lateral ventricle. All experiments were performed in an unanesthetized state at an ambient temperature of 23±2°C.

Drugs used were as follows: l-norepinephrine bitartarate (Wako Chemical
Co.), sodium bitartarate (Kanto Chemical Co.), tartaric acid (Kanto Chemical Co.), propranolol hydrochloride (Sigma Chemical Co.), isoproterenol bitartarate (Sigma Chemical Co.), phenoxybenzamine hydrochloride (Nakarai Chemical Co.) and phenylephrine hydrochloride (Sigma Chemical Co.). Doses of norepinephrine and isoproterenol were calculated on the basis of the free base and other drugs on the basis of the salts.

RESULTS

Effect of intraventricular injection of norepinephrine
As shown in Fig. 1, norepinephrine injected intraventricularly produced a dose-dependent decrease in the rectal temperature. The maximal effect was seen after 15–30 min and the temperature returned to the initial level after 90 min. The repeated injection of this amine (25 μg) resulted in the same decrease in rectal temperature as with the first injection. Hypothermia induced by norepinephrine was associated with a marked rise of skin temperature (Fig. 2). No change was observed in oxygen consumption after the injection of norepinephrine in a dose of 25 μg (Fig. 2). Intraperitoneal injection of norepinephrine in a dose of 300 μg, intraventricular injection of sodium bitartarate and tartaric acid both in a dose 25 μg, and 0.01 N HCl had no effect on the rectal temperature, respectively.

norepinephrine resulted in the same change in rectal temperature as observed in phenoxybenzamine-pretreated rats (Table 1). No change was demonstrated in oxygen consumption when norepinephrine (25 µg) was administered in phenoxybenzamine-pretreated animals (Fig. 3).

The intraventricular injection of alpha-receptor agonist, phenylephrine (6–50 µg), brought about a dose-dependent decrease in the rectal temperature (Figs. 4, 5). The hypothermic effect of phenylephrine was blocked by the prior administration of phenoxybenzamine (Table 2).

On the other hand, beta-receptor blocking agent, propranolol (12.5 µg), given in the same way, showed no effect (Fig. 6). The intraventricular injection of propranolol in a dose of 25 µg prior to norepinephrine (25 µg) abolished the

discussion

Intraventricular injection of norepinephrine in a small dose (6 μg) produced a slight elevation of the rectal temperature, but in larger doses (25–50 μg) resulted in a dose-dependent hypothermia. These results are consistent with others’ findings (Feldberg and Lotti, 1967; Bruinvels, 1970). When norepinephrine was intraperitoneally administered in a dose of 300 μg, no temperature effect was obtained. Moreover, systemic blood pressure did not change following intraventricular injection of norepinephrine in a dose of 25 μg (Abe and Hiroshige, 1974). Accordingly, it would appear that norepinephrine injected into the lateral hypothermia which is normally observed following norepinephrine injection (Fig. 6). But propranolol injected simultaneously with norepinephrine showed no effect (Table 1). Moreover, no dose-response relationship was obtained by the intraventricular injection of beta-receptor agonist, isoproterenol, in doses of 6–50 μg (Fig. 7).

Skin temperature elevation induced by norepinephrine was blocked by phenoxybenzamine pretreatment prior to norepinephrine administration, whereas propranolol had no effect in this respect (Fig. 8).
ventricle acts on the central nervous system directly. In addition, since intraventricular injection of tartaric acid, sodium bitartrate, 0.01 n HCl and isotonic saline had no influence on body temperature, it is inferred that the observed effect is due to the action of norepinephrine itself.

It has been pointed out that these responses are possibly pharmacological artifacts of norepinephrine, since the quantities of intraventricularly injected norepinephrine is considerably large in comparison with the hypothalamic content of norepinephrine. The necessity for high dose of norepinephrine could conceivably be explained by rapid removal of the substance by diffusion into the whole ventricular system, uptake by the capillaries and nerve endings, extracellular binding and metabolism by catechol-O-methyltransferase. So it is presumed that the amount of exogenous norepinephrine which can arrive at postsynaptic receptors is relatively small.

We had reported that 6-hydroxydopamine, imipramine and safrazine produced a fall in the rectal temperature which was similar to that produced by norepinephrine and that norepinephrine-induced hypothermia was more pronounced in rats pretreated with these substances (FUKUSHIMA, 1975). Furthermore, depletion of endogenous norepinephrine by \( \alpha \)-methyl-\( p \)-tyrosine was shown to reduce the thermoregulatory response of norepinephrine (FUKUSHIMA, 1975). These results suggest, therefore, that norepinephrine can influence the thermoregulation rather physiologically; that is intraventricularly injected norepinephrine may act on the postsynaptic receptors in the thermoregulatory neurons.

The existence of central adrenergic receptors resembling peripheral \( \alpha \)-receptor (FISZER and ROBERTIS, 1968) or beta receptor (FORN et al., 1974) has been reported. Chemical stimulation of alpha receptors in the hypothalamus of the rat elicits hunger (BOOTH, 1968; LEIBOWITZ, 1971; BERGER et al., 1971), whereas stimulation of beta receptors in the same region suppresses eating (LEIBOWITZ, 1971).

Our results showed that the effect of intraventricular injection of norepinephrine was diminished by pretreatment with phenoxybenzamine and that a good dose-response relationship was obtained in the rectal temperature changes following intraventricular injection of phenylephrine (6-50 \( \mu \)g). Therefore, it is suggested that norepinephrine produces hypothermia by its action on central alpha receptors in the rat. It is interesting that when norepinephrine was given in phenoxybenzamine-pretreated rats, rectal temperature showed a rise of approximately 1°C. These results are consistent with those reported by BURKS (1972) and RUDY and WOLF (1971) in the cat, NAKAMURA and THOENEN (1971) in the rat and RIGGLE and WOLF (1974) in the golden hamster.

As to beta receptors, no dose-response relationship was obtained by intraventricular injection of isoproterenol. However, the possibility that the beta receptors may participate in the central thermoregulation could not be ruled out, since the prior administration of propranolol in a dose of 25 \( \mu \)g diminished the hypothermia induced by norepinephrine. In this regard, the capability of pro-
pranolol to block alpha as well as beta receptors (Kohl and Ling, 1967; Tsoucaris-Kupffer and Schmitt, 1972) or its considerable depressive and anesthetic actions on the central nervous system (Leszkovszky and Tardos, 1965; Murmann et al., 1966) have been reported. Therefore, these actions may account for the abolishment of norepinephrine-induced hypothermia. On the other hand, Myers and Yaksh (1968) indicated that hyperthermia induced by norepinephrine was mediated by action in central beta receptors. Our above-mentioned observation that norepinephrine could cause an elevation of body temperature in rats with alpha receptors blocked by phenoxybenzamine may suggest the hyperthermic influence of the central beta receptors. Further investigation are necessary to draw the conclusion on the significance of beta receptors in the central thermoregulation.

It is possible that intraventricular norepinephrine has an influence on the hypothalamic blood flow and hypothalamic temperature. Rosendorff (1974) has shown that norepinephrine injected into the hypothalamus in small doses caused an increase in hypothalamic blood flow, while larger doses were vasoconstrictive. This vasodilator effect of norepinephrine was blocked by propranolol and the vasoconstrictive effect was blocked by phenoxybenzamine. It appears thus that the beta receptor was activated by smaller dose of norepinephrine and alpha receptor by larger doses, the net effect of the larger dose being an alpha receptor vasoconstriction. It seems likely that norepinephrine causes a rise of body temperature at smaller doses and a fall at larger doses through its effect on hypothalamic blood flow. In spite of this apparent consistency, Rosendorff could not sufficiently explain the relationship between hypothalamic blood flow and rectal temperature changes in the rabbit (Rosendorff, 1974).

No change in oxygen consumption was observed after the intraventricular injection of norepinephrine. This implies that the norepinephrine-induced hypothermia is not resulted from decreased heat production. On the other hand, the hypothermia was associated with a marked rise of skin temperature which indicates a pronounced peripheral vasodilation. Phenoxybenzamine prevented completely the elevation of skin temperature, whereas propranolol was ineffective. These results clearly indicate that the achievement of the central thermoregulatory mechanism which is responsible for the hypothermia following centrally applied norepinephrine includes the control of peripheral vascular tone in the rat. It is also suggested that the regulation of peripheral vascular tone is mediated by central alpha adrenergic. The involvement of central alpha adrenergic receptors was similarly proposed by Reigle and Wolf (1974) in the golden hamster. These findings indicate that the central alpha adrenergic receptors play an important role in the thermoregulation centrally as well as peripherally.
