The Effect of Small Cell Size on the Sweetness of Cabbage (*Brassica oleracea* L.) Leaves

Yasutaka Kano

*Ishikawa Prefectural University, Nonoichi, Ishikawa 921-8836, Japan*

Head weight of cabbage plants grown using half the nitrogen fertilizer applied to control plants (hereinafter referred to as the half-treatment group) and plants harvested on 22 November (November group) was markedly less than that obtained from control plants to which the standard amount of nitrogen fertilizer was applied and harvested on 29 July (July group). Cells from the half-treatment and the leaves from the November groups were smaller than those of the control and the July groups, respectively. Glucose and fructose content in the half-treatment and the November groups was higher than in the control and the July groups. It is therefore suggested that the higher sugar content in leaves of cabbage plants grown on media containing less nitrogen fertilizer and at low temperature occurs in response to the smaller cells in the leaves.

**Key Words:** *Brassica oleracea* L., cell size, low temperature, nitrogen fertilizer, sugar accumulation.

**Introduction**

Given that increasing the amount of nitrogen fertilizer is a relatively simple method for increasing the yields of leaf vegetables, growers are often inclined to apply more nitrogen fertilizer than is necessary. This increased application of nitrogen fertilizer can cause several problems in the quality of leaf vegetables. For example, oxalic acid, which promotes calculus formation, accumulates in spinach plants in response to increased nitrogen nutrients (Ota and Kagawa, 1996), and sugar content increases in numerous vegetables in response to nitrogen deficiency. In the leaves of cabbage for example, nitrogen deficiency caused an increase in free sugar content, especially that of sucrose (Hara, 1989). Conversely, the sugar content in spinach has been observed to decrease in response to increased application of nitrogen fertilizer (Takebe et al., 1995; Watanabe et al., 1988).

Furthermore, although most cabbage in Japan is cultivated outdoors using several cultivars to ensure year-round production, the nutritive value of cabbage varies at the time of shipping (Yano et al., 1981). Sugar content of cabbage has been observed to vary on an annual basis being low in summer and high during winter (Yano et al., 1981), which suggests that sugar content in cabbage is closely related to the temperature at which cabbage is cultivated. Cabbages with a high sugar content are of particular value for uncooked use, such as for salads.

Kano illustrated that cell size in melon fruit is closely related to sugar accumulation (Kano, 2003, 2004, 2005). Furthermore, sugar accumulation has been observed to increase markedly in fruits that developed at higher temperatures owing to an increase in the number of larger cells (Kano and Fukuoka, 2006). The size of the vacuoles in cabbage leaves decrease during periods of cold acclimation and the sugar content in the leaves increases (Suzuki et al., 1999), suggesting that the sugar content in plant organs is directly related to the size of their cells. Consequently, the manipulation of cell size in cabbage cultivation to produce sweeter cabbage has received considerable interest.

As sugar accumulation in plant organs is closely related with sugar metabolism affected by growing conditions, the effects of nitrogen fertilizer and low temperature on cell size and sugar accumulation in the leaves of cabbage were examined.

**Materials and Methods**

**Plant materials**

**Experiment 1**

Standard nitrogen levels (the control) employed by farmers in Ishikawa Prefecture, Japan for cabbage cultivation, and half the amount of nitrogen used for the control (half-treatment group) were used in this study. The experiments were conducted in a sandy soil field to which barnyard manure was applied at 2000 kg per
10 a in the spring of the previous year. Two fields of 1.4 m wide and 30 m long were employed, with each field divided into two plots. In the control soil, 21 g·m⁻² of N, 29 g·m⁻² of P₂O₅ and 21 g·m⁻² of K₂O were applied as a basal fertilizer, and 5 g·m⁻² of N, P₂O₅ and K₂O and 3 g·m⁻² of N and K₂O were applied as top dressing on 31 May and 16 June, respectively. In the half-treatment soil, 14 g·m⁻² of N, 29 g·m⁻² of P₂O₅ and K₂O were applied as the basal fertilizer with no top dressing. Cabbage seeds (Brassica oleracea L. ‘Wakamine’, Takii Seed Co. Ltd., Kyoto, Japan) were sown in paper pots on 9 May and 28 July. Uniformly sized seedlings were planted in the field on 19 May and 22 September with 0.35 m between the control and half-treatment fields. Five plants were collected on 29 July (July plants) and 22 November from plants sown on 28 July (November plants), respectively. Of the plants sown 9 May, five plants were collected on 29 July (July plants) and 22 November from plants sown on 28 July (November plants), respectively. The third and fourth outermost leaves were collected from the heads of plants in both treatments for analysis of cell number, size, and sugar content.

Experiment 1
Cabbage seeds (B. oleracea L. ‘Okina’, Takii Seed Co. Ltd.) were sown in paper pots on 9 May and 28 July. Uniformly sized seedlings were planted in the field on 19 May and 22 September with 0.35 m between plants. In the field, a basal fertilizer containing 21 g·m⁻² of N, 29 g·m⁻² of P₂O₅ and 21 g·m⁻² of K₂O was applied, and a top dressing containing 5 g·m⁻² of N, P₂O₅ and K₂O and 3 g·m⁻² of N and K₂O was applied on 31 May and 16 June, respectively. Of the plants sown 9 May, five plants were collected on 29 July (July plants) and on 22 November from plants sown on 28 July (November plants), respectively. The third and fourth outermost leaves were collected from the heads of plants in both treatments for analysis of cell number, size, and sugar content.

Measurements of cell number and size in the leaf
Two quadrangular samples weighing approximately 0.3 g were removed using a scalpel from the central portion of the leaf between the main vein and the leaf margin to measure the cell number and size, and for sugar analysis. Each quadrangle was then immersed increasing concentrations of ethanol (70%, 80%, 90%, and 100%), before being infiltrated with normal butanol and embedded in paraffin. Seven 10 µm-thick cross sections were then prepared from these paraffin blocks and the clearest section from each quadrangle for each treatment was then examined under a microscope. Cell size was measured at two locations between the veins in the cross section of one quadrangle. Cells lying on a perpendicular line to the upper leaf surface were counted and measured for their maximum diameter (Fig. 1).

Sugar analysis
Another quadrangle was homogenized in 5 mL of water (Polytron, PT10/35, Kinematica, Littau-luzen, Switzerland) before being centrifuged at 8000 × g for 15 minutes (Iwaki, CFM-100, Tokyo, Japan) and filtered through a 0.45-µm PTFE hydrophilic filter (Millipore, Massachusetts, USA). Forty microliters of the filtrate was injected into an HPLC (Shimadzu Inc., LC-10ADvp, Kyoto, Japan) fitted with a refractive index detector (Shimadzu Inc., RID-10A) with a Shim-pack SCR-101C (Shimadzu Inc.) at 0.8 mL·min⁻¹ at 80°C. To determine the presence and concentrations of each sugar, 40-µL solutions of sucrose, glucose and fructose, each at 20 g·L⁻¹ were injected into the HPLC before injection of the filtrates. In addition, sucrose, glucose and fructose content in the samples in 5 mL of water between boiled and not boiled was not statistically different.

Results
The mean head weight obtained for the half-treatment was 2283 g, which was 523 g less than that of the control (Table 1). The mean weight of leaves from the half-treatment was 45.5 g, which was 11 g less than that of the control. The number of cell layers in the cross section

was approximately 20 in both treatments (data not shown). Cell diameters of the control ranged from 20 µm to 100 µm, while the diameters of the half-treatment cabbages ranged from 20 µm to 80 µm (Fig. 2). The mean cell diameter of the cells from the half-treatment field was 51 µm, which was 4 µm less than that of the control (Table 2). While sucrose was not detected, the mean glucose and fructose contents in all plants from the half-treatment field were 16.2 mg·g⁻¹ FW and 9.9 mg·g⁻¹ FW, respectively, which was 2.6 mg·g⁻¹ FW and 2.0 mg·g⁻¹ FW greater than those observed in the control plants, respectively (Table 3).

**Experiment 2**

Mean daily temperature at the time of planting on 19 May was 17.1°C, which had increased to 28.1°C when the leaves were harvested on 29 July. Conversely, the temperature at the time of planting on 22 September was 24.8°C, which had decreased to 8.9°C when the leaves were harvested on 22 November (Fig. 3). Monthly meteorological information for Ishikawa Prefecture revealed that daily solar radiation fluctuated markedly, but that solar radiation decreased from May to November (Fig. 4). Integrated solar radiation for the November plants from 22 September to 22 November was 565 MJ·m⁻², which was approximately half of that to which the July plants were exposed from 19 May to 29 July.

The mean head weight in November was 2100 g, which was 700 g less than that in July, but the mean leaf weight in November was 65 g, which was twice that observed in July (Table 4). The number of cell layers observed in cross section of the leaves was not significantly different between the July plants and

Fig. 2. Comparison of the size and the number of cells in each plant between grown at standard nitrogen levels and the half of the amount of nitrogen used for the control (left), and between collected on 29 July and 22 November (right). The numbers from 1 to 5 are the plant number used in the experiments.

Fig. 3. Changes in daily mean temperatures during the growing period.
The diameter of cells with the half-treatment and grown during the cold season was smaller than that observed using (control) standard nitrogen levels and grown in the warm season, respectively. While no literature has been published to date illustrating the relationship between cell size and nitrogen concentration in fertilizers, the vacuoles of cabbage leaves treated with low temperature around 1°C have been observed to decrease (Suzuki et al., 1999). The length of parenchymatous tissue cells in leaves from Chinese cabbage grown at low temperatures is less than that obtained in plants grown at high temperatures (Ootake, 1982). Based on these findings, it is reasonable to assume that cells decrease in size in the leaves of cabbage plants grown under relatively low nitrogen fertilizer and temperature conditions.

Glucose and fructose content in the leaves of half-treated plants and those grown under low temperature was higher than that observed in plants cultivated at standard (control) nitrogen levels and high temperature. High nitrogen application to the soil has been observed to produce a decrease in glucose and fructose in cabbage leaves (Yano et al., 1981). Conversely, sucrose, glucose and fructose content in cabbage plants all increased in response to decreased nitrogen levels in culture solution (Hara, 1989), and sugar content in spinach and komatsuna leaves also increased in response to reduced nitrogen application (Takebe et al., 1995). For the effect of low temperature, elevated sugar content has been reported in cabbage harvested in late autumn to winter (Yano et al., 1981). In addition, sugar content has been reported to increase in cabbages cultivated briefly at low temperatures (Koster and Lynch, 1992; Sasaki et al., 1996, 1998; Suzuki et al., 1999). These findings show that glucose and fructose content increase in the leaves of cabbages grown using relatively less nitrogen fertilizer and low temperatures.

Most of the imported sugars then accumulate in the vacuoles of sink-tissue storage cells (Leigh et al., 1979;
Yamaki and Ino, 1992). The numerous and relatively small vacuoles in Okubo peaches during full bloom coalesce to form one large vacuole which forces the cytoplasm to the outside of the mesocarp cell in the middle stage of fruit development (Ishida et al., 1973) and the small vacuoles of the meristematic cells increase in size and gradually coalesce as the cells enlarge and age (Esau, 1964). Eighty percent of the fresh weight of plant tissues is attributable to water, and this exists primarily in the vacuoles. Since small cells can only contain relative small vacuoles, and thus small volumes of water, the sugar content becomes larger in smaller cells if the same amount of assimilated sugars is translocated into cells. Conversely, the similarity observed in assimilated sugar concentrations in both plots of experiment 1 is thought to have been due to the equal amount of integrated solar radiation. The sugars are thus lower in the November group of experiment 2 due to the smaller amount of solar radiation (monthly weather report, Ishikawa Meteorological Agency, 2005).

By putting together these findings, the following assumptions can be made. The higher sugar content observed in the leaves of cabbage plants grown on media containing less nitrogen fertilizer and at lower temperatures can be attributed to reduced cell size in the leaves. Specifically, since cell weight is mostly attributed to vacuole weight, and since water content is low in leaves under conditions of low nitrogen and temperature owing to small cell, the sugar concentration in small cells is high. The sugar content per fresh weight of leaf material under conditions of low nitrogen and temperature is relatively higher owing to a greater number of small cells with higher sugar concentration per fresh weight.
