Abstract : Minimally invasive percutaneous endoscopic discectomy (PED) with a transforaminal approach under local anesthesia was started in the late 20th century. As the procedure requires a skin incision of only 8 mm, it is the least invasive disc surgery procedure at present, and owing to advances in instruments and optics, the use of this technique has gradually spread. In Japan, Dr. Dezawa from Teikyo University Mizonokuchi Hospital introduced this technique in 2003. Thanks to his efforts, the number of surgeons who can perform PED has increased, although the number of active PED surgeons is still only around 20. The first author (K.S.) started PED in 2010. In this review article, we explain the state-of-the-art PED transforaminal technique for minimally invasive disc surgery and present three successful cases. *J. Med. Keywords : *Herniated nucleus pulposus, lumbar spine, surgery, percutaneous endoscopic discectomy, local anesthesia*

INTRODUCTION AND HISTORY

Figure 1 shows a typical magnetic resonance imaging (MRI) of a herniated nucleus pulposus (HNP) of the lumbar spine. The conventional surgical approach to HNP is open removal, which includes laminotomy, flavectomy, and HNP fragment removal, in a procedure known as Love's technique. In the late 20th century, surgeons started to attempt the procedure in a minimally invasive manner under

a microscope and with a special retractor (1). After 1990, the technique was further developed by utilizing a spinal endoscope and a tubular retractor. This endoscope-assisted trans-tubular surgery was eventually established by Foley *et al.* (2) and Dandaneau (3) in what is now known as microendoscopic discectomy (MED). With these procedures, surgeons can access the HNP through the interlaminar space, that is, via the interlaminar approach. Figure 1 shows the site of this approach.

Another means of accessing the intracanal HNP is the transforaminal approach, also shown in Figure 1. The HNP is accessed through the intervertebral foramen (Figure 2). Hijikata (4) started to utilize this approach in what became the conventional technique called percutaneous discectomy. The benefit

of the approach is that it is conducted under local anesthesia with minimal invasiveness. Kambin was another pioneer of this approach (5). However, without an endoscope, it was difficult to remove an HNP located inside the canal. Percutaneous endoscopic discectomy (PED) developed out of these techniques.

From the later 1980s, a trial was started by Kambin, Schreiber, and Leu to utilize an endoscope or arthroscope in the transforaminal approach (6, 7). Thanks to their efforts and to the development of spinal instruments for endoscopic surgery, percutaneous endoscopic lumbar discectomy was established and has since spread worldwide. The establishment of the current single-portal endoscopic discectomy was made possible by the efforts of Yeung *et al.* (8-10). The use of a spinal endoscope improves reliability when removing an HNP compared with Hijikata's conventional technique. Recently, Dezawa and colleagues (11-14) further established an advanced technique using a high-speed drill which enables most HNPs to be removed using a minimally invasive PED system.

In regard to transforaminal surgery in Japan, the technique actually originated with the work of Dr. Hijikata (4), but utilizing the endoscope in his technique was advanced in a number of other countries (6-10). Dr. Dezawa from Teikyo University Mizonokuchi Hospital, Japan adopted this technique in 2003, and thanks to his efforts, the number of PED surgeons in Japan has gradually increased, although as of 2013, the number of active PED surgeons is still only around 20 or so. The first

author (K.S.) started using this technique under Dr. Dezawa's guidance in 2010. In this review article, we explain the state-of-the-art PED transforaminal technique under local anesthesia and present three successful cases.

SURGICAL TECHNIQUE

Surgery is conducted with the patient in the prone position on a standard spine frame. The cannula insertion point is determined before surgery on computed tomography and MRI. The optimum location is 8 to 12 cm from the midline, although this varies among individuals ; for thin patients, around 8 cm from the midline is appropriate. While viewing the C-arm image intensifier, local anesthesia is performed with 1% lidocaine. For safe access to the HNP through the so-called safety triangle (Figure 2), the walking technique is effective. To avoid injuring the nerve root, which exits the cranial side of the intervertebral foramen (Figure 2), the puncture needle must first make contact with the caudal pedicle. Then, using the walking technique, the needle can be safely inserted into the intervertebral disc. This maneuver is called "walking technique", because the needle walks from the pedicle to the disc. This procedure requires 10-15 ml lidocaine : the most important point is to limit the amount of lidocaine near the exiting nerve root. Exposing the exiting nerve root to lidocaine can injure the nerve. Figure 3 indicates the location of the skin incision and the operative scene in transforaminal

PED surgery.

Next, discography is conducted with indigo carmine to dye the nucleus pulposus and herniated mass blue (Figure 4). The annulus fibrosus stays white and the epidural space red due to the presence of vessels. These differences in color clearly differentiate the herniated mass, allowing it to be safely removed. A guide pin is inserted into the disc through the puncture needle, and the obturator and cannula are inserted sequentially through the 8-mm skin incision. After inserting the cannula, the disc fragment at the base of the herniated mass is removed. Then, according to the inside-out and hand-down technique (Figure 5), the cannula is moved toward the epidural space, the herniated mass is removed (Figure 6), and pulsation of the dural tube is confirmed as the indicator of the decompression.

POST-SURGICAL SCHEDULE

The patient can start standing and walking 1-2 h after surgery. Sometimes during local anesthesia, however, lidocaine infiltrates the exiting nerve and the patient experiences numbness, in which case bed rest is needed. Patients are typically discharged the 1 to 3 days after the surgery. Desk work is allowed 4-5 days after surgery, while no heavy labor is permitted for 6-8 weeks to prevent recurrence.

In most cases, sports activity is allowed 5-6 weeks after the surgery. However, returning to contact sports should be carefully determined.

SURGICAL INDICATION

1 : Intracanal HNP at the L1/2 to L4/5 level without migration

This HNP is a good indication for the transforaminal approach. Migrated HNP and HNP at the L5/S1 level are also possible indications ; however, an additional technique is required to remove them.

2 : Migrated HNP

Migrated HNPs are not complete contraindications. However, pediculotomy, which is a technically demanding procedure, is required to remove an upward- or downward-migrated HNP (15). For HNPs that migrate even further into the hidden zone, Dezawa *et al.* proposed the translaminar approach with PED (12).

3 : Intracanal HNP at the L5/S1 level with a high iliac crest

Among the 307 cases reported by Yeung and Tsou (9), over 50% had an HNP at the L5/S1 level. In so-called “high iliac” cases, the iliac crest can hinder level insertion of the cannula through the intervertebral foramen. Therefore, the standard technique cannot be applied and the cannula cannot be inserted into the canal at the appropriate position. To address this issue, Lee *et al.* (16) proposed the foraminoplastic approach, which enables the cannula to be inserted at the appropriate position after enlarging the intervertebral foramen by foraminoplasty.

Moreover, to remove the HNP from this location, small incised MED using PED system should be selected (11).

4 : Far-lateral HNP

For an HNP located outside the canal, the cannula can be inserted directly into the HNP, making it comparatively easy to remove the mass since there is no need to insert the cannula through the intervertebral foramen. In fact, a far-lateral HNP can be removed at all lumbar levels by the posterolateral approach under local anesthesia (17, 18).

5 : Recurrent HNP

Safely removing a recurrent HNP at the same level by Love's or micro-Love's technique or MED is technically demanding due to adhesions and scar tissue surrounding the nerve root and HNP. For PED, the transforaminal approach can be performed as the initial operation, which is the strength of this approach. Ruetten *et al.* commented on the usefulness of PED for recurrent HNP based on their experience of 463 cases (19) and subsequently reported its utility (20). Shin *et al.* (21) conducted revision PED surgery for 41 cases of recurrent HNP after conventional open surgery and reported good to excellent outcomes in over 90% of cases.

CLINICAL OUTCOME

The clinical outcome of the present technique was first reported by Yeung and Tsou (9). Of the 307 cases of PED surgery they performed, about 90% had satisfactory results, which is equivalent to the rate of favorable outcomes in conventional open surgery. Ruetten *et al.* (22) compared this technique with microdiscectomy and found that the clinical results were comparable in both kinds of surgery, since after endoscopic surgery 82% of the patients no longer had leg pain and 14% had only occasional pain.

Birkenmaier *et al.* (23) reviewed five comparative studies of the present technique and conventional open surgery and concluded that PED had similar clinical outcomes. Moreover, they emphasized the following benefits of PED : shorter operating time, lower estimated blood loss during surgery, fewer surgery-related complications, less surgical site pain immediately after surgery, less need for postoperative pain medication, shorter hospital stay, and a faster return to work.

COMPLICATIONS

Surgery-related complications are listed in Table 1. Among them, injury to the exiting nerve root is a notable complication of the transforaminal approach, but is very rare when using an interlaminar approach such as Love's technique or MED. This injury occurs in 1.0-8.9% of cases (24) and there are two possible causes. The first is direct injury by a cannula. When lidocaine infiltrates the exiting nerve root, the patient does not feel any pain, despite injury to the nerve. As a result, dysesthesia and motor paresis will occur just after the surgery. In our initial 100 cases, no patients had this complication as local anesthesia had been carefully performed. The second possible cause is irritation of the dorsal root ganglion due to compression by the cannula during surgery. In this case, dysesthesia of the lower limb develops a couple of days after surgery. In our initial 100 cases, two patients complained of leg pain and dysesthesia 2 days after surgery, although the pain disappeared within 3 months after treatment with medication.

Table 1 : Complications during and after percutaneous endoscopic discectomy with the transforaminal approach.

General Complication	
Nerve root injury	Cauda equina injury
Dural tear	Hematoma
Surgical site infection	Major vessel injury
Specific Complication	
Exiting nerve root injury	
Intracranial hypertension	
(Neck pain, headache, convulsion, seizure, death)	
Kidney or colon injury	

Another important complication which surgeons must be aware of is intracranial hypertension during surgery, which may result in headache, seizure, or even death. Choi *et al.* (25) reported 4 cases of seizure among 16,725 cases of PED. The patients complained of neck pain before seizure and therefore neck pain was regarded as an indicator of the consequent seizure. In our initial 100 cases, 2 patients complained of neck pain during surgery. Therefore, we completed surgery as soon as possible and did not experience any further complications such as seizure. Neck pain is an important warning sign of serious complications that can arise from high cranial pressure.

CASE PRESENTATION

Case 1

Figure 7 shows MRI scans before and after surgery in a 32-year-old male handball player who was not able to play handball due to a herniated mass compressing the L5 nerve root. The mass was removed by PED with the transforaminal approach (Figure 8), and his low back pain disappeared. Within 4 weeks after surgery, stretching and trunk core isometric exercises were started with the assistance of his athletic trainer. From 4 to 8 weeks, mild throwing exercises and jogging were permitted. Eight weeks after the operation, he made

a full return to sports activity, including contact sports. To date, he has been active in sports for 6 months after the surgery.

Case 2

Figure 9 shows MRI scans before and after PED surgery in a 29-year-old man who had received conventional open surgery for an HNP at the L4/5 level 7 years earlier. When similar symptoms appeared, he visited us and was treated by PED under local anesthesia. The next afternoon, he returned to his sedentary job. The difference in the length of the incisional scar compared with the conventional open procedure is obvious (Figure 10).

Figure 8 : Herniated fragment removal in Case 1.

Figure 9 : T2-weighted axial view before and after surgery in Case 2.

Figure 10 : Skin incisional scar in Case 2 after Love's method and PED.

Case 3

Figure 11 shows MRI scans before and after PED surgery in a 40-year-old woman who had received micro-Love surgery for an HNP at the L4/5 level 20 years earlier. After carrying a heavy package, she experienced severe leg pain. A recurrent HNP at the same level was diagnosed for which she underwent PED surgery. The HNP fragment had migrated slightly in the caudal direction. After partial cranial pediculotomy, a cannula was inserted cranially and the migrated mass was removed (Figure 12). The incisional scar of the micro-Love procedure was 3 cm and that of PED was 8 mm (Figure 12).

Figure 11 : T2-weighted sagittal view before and after surgery in Case 3.

Figure 12 : Skin incisional scar in Case 3 and intraoperative X-ray. Note the difference in surgical scar size between Love's method and PED. The X-ray shows the location of the rongeur after partial pediculectomy.

FUTURE PERSPECTIVES

Two kinds of new approaches using PED have been introduced. One is laminectomy with a high-speed drill for lumbar spinal canal stenosis (26) and the other is radiofrequency thermal annuloplasty for discogenic low back pain (14, 27). However, neither approach has been widely used to date. Therefore, the benefits and details of these new technologies should be disseminated by technical educational seminars using fresh cadaveric spines.
