Cholecystitis Caused by Infiltration of Immature Myeloid Cells:  
A Case Report

Abstract

A 59-year-old man with myelodysplastic syndrome who was hospitalized for evaluation of  
fever and generalized fatigue had elevated levels of C-reactive protein and pancytopenia. A  
search for a site of infection and empiric treatment with antibiotics were unsuccessful. Over 5  
to 6 weeks right upper quadrant pain and rebound tenderness developed. Sonographic  
Murphy's sign was present. Computed tomography showed thickening of the gallbladder wall,  
and repeated ultrasonography demonstrated changes consistent with cholecystitis. Open  
cholecystectomy was performed as an emergency procedure. Macroscopically the resected  
gallbladder showed an edematous and thickened wall. Histopathologic examination revealed  
transmural infiltration by atypical mononuclear cells with distinct nuclei. The cells showed  
immunohistochemical staining for CD15, indicating myeloid lineage. By 10 days after surgery,  
counts of leukocytes and leukoblasts had markedly increased, reaching 36,700/µL and 76.0%,  
respectively. The blast crisis was thought to indicate progression from myelodysplastic  
syndrome to leukemia. The patient died of progressive disease 12 days after surgery. We have  
described a rare case of acute cholecystitis caused by infiltration of immature myloid cells to  
the gallbladder. An acute abdomen complicating hematologic disorders is life-threatening and  
requires prompt and appropriate treatment.

Key words: cholecystitis, myelodysplastic syndrome, leukemic transformation

Introduction

The clinical course of patients with hematologic disorders is often complicated by events presenting  
as an acute abdomen¹. Although the gastrointestinal tract may be involved by hematological diseases,  
such as leukemia, blast cell infiltration of the gallbladder is extremely rare².  

We describe a patient with acute cholecystitis caused by infiltration of immature myloid lineage  
cells to the gallbladder wall.
Case Report

A 59-year-old man with myelodysplastic syndrome (MDS) was admitted to the internal medicine service at our hospital for evaluation of pyrexia and generalized fatigue. Initial laboratory tests showed elevation of C-reactive protein (10.18 mg/dl) and pancytopenia (leukocyte count, 2,900 /µl with 14.0% blasts, 0.0% neutrophils, 19.5% lymphocytes, and 18.0% monocytes; red blood cell count, 167 × 10^6 /µl with a hemoglobin value of 5.4 g/dl and a hematocrit of 15.3%, and a platelet count of 36,000 /µl). Pyrexia and elevated levels of C-reactive protein indicated infection, but both a search for a site of infection and treatment with antibiotics were unsuccessful. Although C-reactive protein decreased transiently with broad-spectrum antibiotic treatment, the fever persisted. Pancytopenia was treated with transfusions of red blood cells and platelets, and the infection was treated with injections of granulocyte colony-stimulating factor (G-CSF).

On the 36th hospital day, the patient complained of mild pain in the right upper quadrant. This pain gradually worsened until the 45th hospital day, when guarding and rebound tenderness developed over the gallbladder and the patient was referred to the department of surgery. Physical examination then disclosed palpable enlargement of the liver and tenderness over the gallbladder. Murphy’s sign was present.

Ultrasonography showed gallbladder wall thickening and a hyperechoic 2-cm gallstone. Gallbladder distention, intrahepatic bile duct dilation, and fluid accumulation around the gallbladder were not seen. Severe pain was elicited by pressure of the transducer over the gallbladder.

Abdominal computed tomography (CT) demonstrated a diffusely thickened gallbladder wall, a calcified 2.5-cm gallstone (Fig. 1), and marked hepatosplenomegaly.

Percutaneous biliary drainage could not be performed because neither the gallbladder nor the intrahepatic biliary tree was dilated. Open cholecystectomy was performed as an emergency procedure on the 45th hospital day. Marked hepatomegaly and edema of the gallbladder were seen, but accompanying inflammatory findings, such as adhesion and distension of the gallbladder, were not prominent.

Macroscopically the resected gallbladder showed an edematous and thickened wall and contained two 2.5-cm gallstones (Fig. 2). Histopathologic examination of this specimen at low magnification showed intramural infiltration of atypical mononuclear cells (Fig. 3A). At high magnification this area showed atypical blastoid cells with distinct nuclei (Fig. 3B). The cells demonstrated immunohistochemical staining for CD15, suggesting myeloid lineage (Fig. 3C). These immature myeloid cells presumably were the cause of cholecystitis. Cultures of bile and blood obtained intraoperatively were negative for bacteria, because broad-spectrum antibiotic treatment had continued.
Fig. 3: Histopathologic examination of this specimen at low magnification showed intramural infiltration of atypical mononuclear cells (hematoxylin-eosin, ×50). B: Examination of this area at high magnification revealed atypical blastoid cells with distinct nuclei (hematoxylin-eosin, ×400). C: The cells demonstrated immunohistochemical staining for CD15, suggesting myeloid lineage cells. (×200)

The persistent fever did not resolve after surgery. On day 10 after surgery, counts of leukocytes and blasts were greatly increased, reaching 36,700/µl and 76.0%, respectively (Fig. 4), while erythrocytopenia and thrombocytopenia worsened. The blast crisis was thought to indicate progression from MDS to leukemia. Myelosuppressive chemotherapy failed to affect the clinical condition or laboratory abnormalities. Severe pneumonia developed, with subsequent disseminated intravascular coagulopathy and multiple organ failure. The patient died 12 days after surgery.

Discussion

Acute abdominal complications are not rare in patients with hematologic disorders. Hawkins et al. have found acute abdominal disorders in 5.3% of 412 patients with acute leukemia. Blast cell infiltration of the gastrointestinal tract can occur, but gallbladder infiltration is reportedly rare. Several case reports describe relapse of acute lymphoblastic leukemia presenting as leukemic infiltration of the gallbladder wall. Recently, de novo acute leukemia was reported to present as symptomatic gallbladder involvement. Cholecystitis related to chemotherapy is reported to occur in a significant proportion of patients with acute leukemia. Gorschluter et al. have reported cholecystitis in 4.8% of patients with leukemia undergoing chemotherapy. Acalculous cholecystitis may be associated with physiologic and pathophysiologic stresses, such as major surgery, multiple injuries, burns, sepsis, childbirth, and blast cell infiltration. Although stones were present in this case, blast cell infiltration may have been the main cause of cholecystitis, considering the severe immature myeloid cell infiltration seen at autopsy.
Patients with MDS commonly have refractory anemia accompanied by various degrees of granulocytopenia and thrombocytopenia. The G-CSF used in this case is effective for increasing the granulocyte count and for treating infections, but MDS includes potentially malignant bone marrow disorders, and G-CSF might provoke progression to leukemia. The prognosis of MDS is variable and depends on the presence of infection and the progression of leukemia.

Abdominal complications in patients with hematologic disorders can be life-threatening. A report from the 1970s indicated that without surgery, intrabdominal complications in patients with leukemia are nearly always fatal. Emergency surgery when patients with leukemia present with an acute abdomen is also associated with high reported mortality rates. Vaught et al have found all deaths after surgery to have resulted from uncontrolled sepsis.

Because patients with hematologic disorders are severely immunocompromised, treatment of infection with intensive antibiotic therapy is extremely important after surgery. Although the timing and indications for surgery in these patients remain controversial, the role of surgical treatment remains controverial. Chirletti et al have advocated prompt surgical treatment in the presence of an acute abdomen and have suggested that appropriate early surgery contributes to general recovery; the operative mortality rate in their patients with hematologic disorders was 5.5%. If a patient’s general condition does not permit immediate surgery, intensive preoperative care is required to prepare the patient for surgery.

We have described a rare case of acute cholecystitis in a patient with MDS. An acute abdomen complicating hematologic disorders is life-threatening and requires prompt, appropriate treatment.
