Abstract

Lipoma of the finger is rare, and there have been few case reports of lipoma causing bone erosion in the finger. We report on a patient with a long-standing lipoma that caused deep erosion of the distal phalanx of the index finger. A 38-year-old man presented with a painful mass of the left index finger. Anteroposterior radiographic images showed a radiolucent area in slightly distal to the center of the distal phalanx. Magnetic resonance imaging revealed a large soft-tissue mass with high signal intensities and slight irregularity on both T1- and T2-weighted images which suggested lipoma. The patient underwent marginal excision of this tumor and curettage of the bone surface of the erosion. The pain resolved after surgery. The diagnosis of lipoma was confirmed with postoperative histological examination. Lipoma should be included in the differential diagnoses of a finger tumor, even if radiography shows bone erosion.

(J Nippon Med Sch 2012; 79: 307–311)

Key words: lipoma, hand, finger, bone change

Introduction

Lipoma is a common soft tissue tumor that can occur in any part of the body. However, lipoma rarely occurs in the finger and rarely causes bone erosion. There have been a few case reports of lipoma causing bone erosion in the finger^{1–3}. We report on a patient with a long-standing lipoma that caused deep erosion of the distal phalanx of the index finger. Differential diagnoses for this lesion are discussed.

Case Report

A 38-year-old man presented with a mass of the left index finger. The mass had slowly enlarged over approximately 18 years and had been painful for the previous 2 years. There was no history of trauma to the hand. His medical history was unremarkable. On physical examination, a mass covered with pink, thin, taut skin was detected on the pulp of the index finger (**Fig. 1**). Superficial dilated veins were observed through the skin. The mass was painful, relatively firm, and immobile. The nail was elevated and convex, and the nail bed was pale. The range of

motion of the distal interphalangeal joint was restricted (0–30°). No sensation disturbance was found in the finger.

Anteroposterior radiographic images showed a radiolucent area slightly distal of the center of the

distal phalanx. This area was round and resembled an enlarged vessel foramen, although no vessel foramen of the distal phalanx was observed on the unaffected side (**Fig. 2**). On a lateral view, a deep, narrow bone erosion was observed to extend into the medullary space with a sclerotic peripheral margin. Magnetic resonance imaging revealed a large soft-tissue mass with high signal intensities and slight irregularity on both T1- and T2-weighted images which suggested lipoma (**Fig. 3**). The lesion was present on both the palmar and dorsal sides of the distal phalanx and extended proximally to the palmar soft tissue between the distal and middle finger creases. The lesion also extended into the medullary space through the palmar cortex, but whether it penetrated through the dorsal cortex was unclear. Fine-needle aspiration biopsy showed many mature perivascular adipocytes, which also suggested lipoma.

The patient underwent marginal excision of this tumor and curettage of the bone surface of the erosion. At surgery, a soft yellow mass was observed under the skin. The mass was lobular and extended into the bone through the palmar cortex of the distal phalanx but did not penetrate the dorsal cortex of the phalanx. The lesion also extended to

the dorsal side along the radial surface of the distal phalanx (**Fig. 4**) and was partially adherent to the periosteum. The lesion was easily excised because it did not adhere to the surface of the eroded area. The lesion measured $31 \times 26 \times 12$ mm. A deep bone erosion was observed on the palmar aspect of the distal phalanx (**Fig. 5**). Hyperostotic changes, such as

osseous projection, were not found. The diagnosis of lipoma was confirmed with postoperative histological examination (**Fig. 6**). This examination showed that fibrous tissues were slightly more prevalent than in a typical lipoma. No atypical lipoblasts were observed. The pain resolved after surgery. There was no recurrence during the 1 year of follow-up.

Discussion

Lipoma of the finger is rare. To the best of our knowledge, fewer than 30 cases have been reported¹⁻¹³. According to detailed reports of 13 lesions, the mean age of the patients was 54; females were slightly predominant; almost all patients had symptoms, such as pain and restricted range of motion; the mean interval between tumor awareness and consultation was 90 months; and tumors did not recur¹⁻¹³.

To the best of our knowledge, only 3 lipomas of the finger associated with bone changes have been reported¹⁻³. These were a lipoma causing bone erosion and 2 parosteal lipomas¹⁻³. Stein² reported on a 70-year-old man who had a large lump that filled most of the pulp of the thumb. Radiographic images showed a destructive lesion of the distal phalanx. At surgery, there was a small opening into the distal phalanx and multiple loculated areas in the phalanx similar to a honeycomb stone. The lesion was histologically diagnosed as a lipoma. Stein² could not determine whether this lipoma had arisen from the pulp of the thumb and invaded the bone or had arisen from the bone and invaded the soft tissues. Therefore, intraosseous lipoma that had invaded the soft tissue could also have been included in the differential diagnosis of the present case. In general, intraosseous lipoma is radiologically visualized as a lytic lesion with trabeculation and

may be accompanied by bone expansion and cortical thinning¹⁴. The present lesion did not show trabeculation, bone expansion, or cortical thinning. In addition, the intraosseous portion of the present lesion was much smaller than the soft-tissue portion. The bone changes associated with the present lesion are not consistent with those associated with intraosseous lipoma.

Parosteal lipoma is a lipoma arising on the bone surface^{3,15}. This tumor usually has a broad-based attachment to the subjacent bone and no continuity with the medullary cavities^{3,15}. Parosteal lipoma is also usually associated with irregular osseous excrescence into the soft tissue. One of the 2 reported cases was in a 68-year-old woman with a parosteal lipoma at the tip of the fifth finger³. Radiographic images showed an osseous projection, cortical irregularity, and hyperostosis of the distal phalanx³. These findings were typical of parosteal lipoma. The other case was in a 64-year-old man with a parosteal lipoma of the index finger. This lesion had caused a subtle erosion of the cortex on radiographic images⁴. Regarding the lesion of the present case, its attachment to the phalanx was narrow-based, its extension into the medullary cavities was deep, and it had no association with irregular osseous excrescence. These findings are not consistent with parosteal lipoma. This lesion seemed to be under a high internal pressure, as indicated by the tense skin. The partial adherence of the lesion to the periosteum observed at surgery could be associated with either a parosteal lipoma or a large lipoma. We believe that the present lesion was a long-standing lipoma that had caused deep bone erosion in the finger where the space is limited for tumor growth. Lipoma should be included in the differential diagnosis of a finger tumor, even when bone erosion is seen on radiographs.
