Key words: mercury/copper/oral microorganisms/adsorption

Abstract: The metal ion accumulation by oral bacterial cells was investigated in this study using two heavy metals, copper and mercury at pH 4.0 and 7.0. However, the adsorption rate of mercury was especially examined at pH 4.0 because of the loss of metal ions caused by the adsorption on the walls of the container and the occurrence of volatilization at pH value on the neutral and alkaline side.

Higher mercury adsorption by bacterial cells were demonstrated in Propionibacterium acnes, Treponema denticola and Eikenella corrodens in order of strength at pH 4.0. Regarding copper ion adsorption by oral bacteria, the higher metal adsorptions were also shown at pH 4.0 and 7.0 in P. acnes, Peptostreptococcus anaerobius and Corynebacterium matruchotii, respectively.

The metal adsorptive abilities of these oral microorganisms appeared to be higher than that of Actinomyces levoris which had extremely high uranium accumulation abilities etc.

There were no marked differences between the intact cells and the lyophilized cells of P. acnes, even when treated with heat at 100°C for 10 min.

These metal ion adsorptions by microorganisms always proceeded immediately after adding metal to bacterial suspension and reached a plateau around 5 min later.

These findings obtained strongly suggest that some oral bacteria have the potential the adsorption of heavy metal ions, and that the mode of adsorption is based on a physico-chemical action governed by the Freundlich adsorption isotherm equation.
Introduction

More than twenty heavy metals have widely been applied and used as restorative materials such as amalgams and alloys in dental clinics. Most are thought to be non-toxic but a few sometimes exhibit toxicity to the human body.

It has been suggested that several heavy metal elements might be released from amalgams and alloys resulting in toxicity and allergenicity.

On the other hand, it is recognized that many kinds of heavy metals are capable of being adsorbed and accumulated to biomass such as bacteria, algae, fungi, yeast and even dead cells and their products. In the oral cavity, many kinds of oral bacteria are able to colonize on the teeth, in subgingival crevices and gingival pockets to produce supra and subgingival plaque. This dental plaque sometimes results in dental caries and periodontal diseases associated with carbohydrate ingestion. Considering such points most dentists have thought that the plaque should be removed by brushing and flossing. On the contrary, it may be presumed that dental plaque is a sort of bacterial film and acts as a barrier in defence of the oral ecosystem.

However, the intrinsic biological role of these normal flora is still not fully known.

The purpose of this investigation was to demonstrate and elucidate the heavy metal ion-adsorption by the oral flora. The adsorbing characteristics of two heavy metals, mercury and copper were studied.

Materials and Methods

Organisms

Ten strains, Actinomyces levoris HUT 6156, A. naeslundii ATCC 12104, Corynebacterium matruchotii ATCC 14622, Eikenella corrodens ATCC 10596, Fusobacterium nucleatum ATCC 10539, Peptostreptococcus anaerobius ATCC 27377, Porphyromonas gingivalis ATCC 33277, Propionibacterium acnes ATCC 6919, Treponema denticola ATCC 33520 and Streptococcus mutans LM-7 were subcultured and used for this experiment.

The purpose of this investigation was to demonstrate and elucidate the heavy metal ion-adsorption by the oral flora. The adsorbing characteristics of two heavy metals, mercury and copper were studied.

Table 1. These microorganisms except A. levoris are easily isolated from the oral cavities of most individuals.

Metal ions

Two metals, copper and mercury were purchased from Nakalai Tesque Inc. Kyoto in a ionic state. Copper standard solution (stock solution, Cu 1,000 ppm, CuSO₄ in 0.1 mol of HNO₃) was diluted with distilled water and adjusted to pH 4.0 and 7.0 with 0.1N NaOH and 0.1N HNO₃ solution. Mercury standard solution (stock solution, Hg 1,000 ppm, HgCl₂ in water) was also diluted with distilled water and adjusted as above.

Culture

A. levoris was aerobically subcultured in a liquid medium consisting of 3 g meat extract, 5 g peptone and 5 g of NaCl per liter (pH 7.0) at 37°C for 24 hr. A. naeslundii was aerobically cultured in brain heart infusion (BHI) broth (BBL, Microbiology systems, pH 7.0) at 37°C for 24 hr. C. matruchotii and S. mutans were aerobically cultured in BHI broth supplemented with 0.2% yeast extract at 37°C for 24 hr. Several anaerobes, P. anaerobius, P. acnes, E. corrodens and F. nucleatum were anaerobically cultured in GAM (Gifu Anaerobic Medium, Nittsui, pH 7.0) at 37°C for 48 hr. P. gingivalis was also cultured in GAM supplemented with hemine (1%) and menadione (0.1%, pH 7.0). T. denticola was anaerobically cultured in TYGVS (trypticase soy, yeast extract, volatile, fatty acids, and serum, pH 7.2) at 37°C for 7 days.

Lyophilized cells

After cultivation, each bacterial cell was centrifuged at 6,000 g for 30 min, and washed 3 times with distilled water. The harvested cells were lyophilized, and kept in a freezer until use.

Viable cells

The P. acnes cells grown in GAM medium were immediately harvested, and washed with distilled water and centrifuged at 2,500 rpm. The cell concentration was adjusted with distilled water to make a final concentration of 7.37×10¹ⁱ cells/ml by using a
bacterial cell counter (Petroff-Hausser, U. S. A.).

**Heat-killed cells**

Lyophilized cells: The cells of lyophilized *P. acnes* were treated in boiling water for 10 min. The cell concentration was adjusted with distilled water to make a final concentration of 1 mg/ml.

Viable cells: The cells of grown *P. acnes* were harvested and treated in the same manner as above. The cell concentration was adjusted with water to make a final concentration of $7.37 \times 10^{11}$ cells/ml by using bacteria counter (Petroff-Hausser, U. S. A.).

**Adsorption experiments**

All glass test tubes and polypropylene tubes were immersed in 1N HNO$_3$ solution for 4hr and rinsed several times with deionized water before use to avoid metal contamination.

In the mercury adsorption test, the cells (20 mg dry weight) were suspended in 10 ml of distilled water. An amount of 0.5 ml bacterial suspension was mixed in 4.5 ml of Hg (a final concentration of 0.45 µg/ml, 2.24 µM) solution. In the copper adsorption test, an amount of 0.5 ml bacterial suspension was mixed in 2 ml of Cu (a final concentration of 1.6 µg/ml : 25.2 µM) solution. The pH of the aqueous solution was adjusted to pH 3.0 to 8.0 with 0.1M HNO$_3$ and 0.1M NaOH solution$.^6$ After each suspension was incubated and stirred for 1hr at 37°C, each solution was centrifuged for 30 min at 23,000 g and the supernatant was collected. The amounts of free metal ions in the supernatants were determined by atomic adsorption spectrometer (Shimadzu AA660). The adsorption rate was determined as the following formula: the rate = (Initial metal concentration − Residual metal concentration in the solution)/Initial metal concentration in the solution) $\times 100$.

**Mercury assay**

The mercury measurements were carried out with a flameless atomic adsorption spectrometer equipped with a cold vaporizer of mercury (MVU-1A, Shimadzu). The cold-vapor technique by Ebbestad U et al$^{10)}$ was modified. With a syringe, 2.5 ml of a 10% SnCl$_2$ solution in 1N H$_2$SO$_4$ was injected through the septum. The apparatus was calibrated for each type of sample using acidified and stabilized mercury stock solution$^{11-13)}$.

**Copper assay**

The analysis for copper was carried out with an atomic adsorption spectrometer (Shimadzu AA660) over an acetylene flame$^{14)}$.

**Adsorption isotherm of metal ions by bacteria**

Adsorption reaction has been characterized by an adsorption isotherm. Many isotherms of adsorption reaction have been proposed, but the Freundlich appeared to be most universally accepted.

The effect of the metal concentration in the solution on copper adsorption by *P. acnes* was examined. The lyophilized cells of *P. acnes* at a final concentration of 0.2 mg/ml was suspended and incubated with four different concentrations of copper (10 to 500 µg/ml) at 37°C for 1hr, and the copper ions adsorbed by the cells were measured and estimated in relation to their concentration in the solution.

**Statistical analysis**

Analysis of variance for multiple comparisons was used for assessment of the statistical relevance of the results. The adsorption test was repeated 7 times on the recovery rate of the mercuric and copper ions.

**Results**

**Mercury stability at various pHs**

The recovery of the mercuric ions was markedly affected by the pH range (Fig. 1). At the pH values above 5 to 8, the mercury recovery rate was markedly reduced. However, at the pH 4.0 the recovery was about 100%. On the other hand, the recovery of copper ions was not markedly affected by the pH of the solution (data not shown). The mercury-adsorbing abilities were examined and compared with pH 4.0 and 7.0 range.

Also, the adsorption rate of copper ions was examined at both the 4.0 and the 7.0 range.

The heated-killed cells of P. acnes were prepared by immersing the lyophilized cells in boiling water for 10 min. The concentrations of the cells used for adsorption test were adjusted to make a final concentration of 1 mg/ml by measuring dry weight.

Adsorption of metal ions by various microorganisms

The adsorption rate of mercuric ions in each bacterial suspension of double dilution series was examined at pH 4.0 (Fig. 4). With a final concentration of the microorganisms at 0.1 mg/ml, the rate of adsorption by P. acnes, T. denticola and E. corrodens were about 90% and were most effective on the mercuric ions. The rate by A. levoris showed 70% and that by C. matruchotii was about 20%.

The rate of copper ion adsorption by various microorganisms at pH 4.0 is shown in Figure 5. With a final concentration of the microorganisms at 0.4 mg/ml, the rate by T. denticola, P. anaerobius and C. matruchotii were about 80%, and were most effective on copper ion adsorption. A. levoris and P. acnes showed the rate of about 75%. The rates of adsorption by...

Fig. 8 Freundlich isotherm equation for adsorption of copper ions by P. acnes.

Adsorption experiment was carried out by suspending the cells (dry weight, 4 mg) in 2.5 ml copper solution (pH7.0).

T. denticola and E. corrodens.

**Adsorption of metal ions by non-heat cells and heat killed cells**

With the viable cells immediately after the culture of P. acnes, the adsorption rate of copper by the viable cells was decreased by about 6.4% by heat treatment at pH 7.0 (Fig. 2), but the rates of the decrease was insignificant.

On the other hand, there were no differences between the lyophilized cells and their heated cells regarding the amount of metal ions.

With the lyophilized cells, the rates of the two metal ions were not decreased by the heat treatment at pH 4.0 (Fig. 3). The mercuric and copper ions-adsorbing abilities of the heat-killed cells and non-heat lyophilized cells were similar.

**Time course of the adsorption of metal ions by P. acnes**

The time course of the adsorption of mercuric and copper ions by P. acnes was examined at pH 4.0. The adsorption of mercuric and copper ions by P. acnes reached a plateau 5 min after addition of the metal ions and did not increase thereafter (Fig. 7). This rapid adsorption of metal ions by P. acnes was similar to that observed with A. levorit15).

**Adsorption of copper by P. acnes according to Freundlich isotherm**

The adsorption experiment was carried out by suspending the cells (4 mg of dry weight) in 2.5 ml of copper solution at pH 7.0, to make four dilution series. The amount of copper adsorbed at these four concentration levels formed a straight line on a log-log graph (Fig. 8).

**Statistical analysis**

Significant differences between the mean control and mean experimental counts were determined by using the coefficient of variance. On both copper and mercury, the 95% confidence limit extended to 2.8% of the mean adsorption value with the means at 7 times. Therefore, standard errors were less than 2.8% in each case.
Discussion

The adsorption of mercuric and copper ions by oral microorganisms was studied. The assays were conducted under similar conditions as to pH and temperature in the environment of the oral cavity. The temperature was set at 37°C. However, the pH of the solution for mercury assay was set at 4.0 because mercury in general tends to volatilize at pH 7.0 but not at pH 4.0 (Fig. 1) thereby allowing sufficient recovery. On the other hand, the copper measurements were easily carried out at both pH 4.0 and 7.0 because of non-volatility. In this experiment the amounts of bacteria were estimated as the dry weight of the lyophilized cells. This is because there were almost no differences between the adsorbing abilities of the lyophilized and viable cells, and estimation by using the dry weight was easier than using a bacterial counter for the comparison of metal adsorption with another bacteria (Fig. 4-6).

The effects of the lyophilized cell concentrations of oral bacteria on metal adsorption were examined. At pH 4.0 with the concentration of the microorganisms at 0.1 mg/ml, mercury-adsorption higher than 80% was observed in P. acnes, E. corrodens and T. denticola (Fig. 4). Besides, with the final concentration of the microorganisms at 0.4 mg/ml, all T. denticola, P.anaerobius and C. matruchotii showed over 80% adsorption of copper adsorption in ratio (Fig. 5). At pH 7.0, copper-adsorption by C. matruchotii, P.acnes and P.anaerobius was observed exceeding 80% (Fig. 6).

It has been reported that the genus Actinomyces differs from many other bacteria and has a high adsorptive ability of uranium and mercury. However, the results obtained in these experiments indicated that the mercury-adsorbing abilities of A. levoris and A. naeslundii species were less than those of E.corrodens, F. nucleatum, P. anaerobius and T. denticola for mercury at pH 4.0 and of C.matruchotii, P. anaerobius and T. denticola for copper at pH 7.0. It appears that metal-adsorption may differ markedly among bacterial species.

These results suggest that the Actinomyces may not be the only genus having high mercury and copper-adsorbing abilities.

Cells of these microorganisms were Gram-negative or positive, and were cocci or rods morphologically (Table 1). Like most cell surfaces, the bacterial cell wall is anionically charged. Most cell walls of Gram-positive bacteria contain relatively large amounts of peptidoglycan and an anionic polymer, such as a teichoic or a teichuronic acid. All walls of Gram-positive bacteria are negatively charged in media capable of supporting growth. On the other hand, the envelope of Gram-negative bacteria is, however, more complex than that of its Gram-positive counterpart.

It seems that there may be some differences in the structure of the cell walls between Gram-negative and-positive bacteria, as they effect metal-adsorbing abilities. However, the results obtained suggest that neither the differences of Gram stain ability nor of morphology are related to the metal-adsorption of microorganisms.

There were marked differences in the adsorbing-abilities between mercuric and copper ions by C. matruchotii (Fig. 4~6). In addition, the significant differences in the adsorption of copper ions by T.denticola at the two pH points between pH 4.0 and 7.0, were observed. However, the modes of adsorptive action remains unknown.

It has been previously reported that some elemental metals, nickel and mercury, etc. released from dental amalgam and alloys might exhibit toxicity to human bodies while, several researchers have pointed out that enough indirect evidence exists to assume the passivity of amalgams in the oral cavity. Thus reducing the risk of factors regarding of mercury or copper.

From these points of view, the adsorption rates of mercuric and copper ions by oral bacteria derived from human dental plaque were examined.

In the adsorption of the mercuric ions at pH 4.0, the adsorption rates by P. acnes, T. denticola and E.corrodens were highest among all species tested. For copper adsorption at pH 4.0, T. denticola, P.anaerobius and C.matruchotii showed the highest rates in all species tested.

The adsorption of copper by agarose used as a
control was about 20% lower than that of the microorganisms (Figs. 5, 6). As the polysaccharide such as agarose had some metal-adsorbing ability, the true adsorption of metal by bacteria should be compared with that of agarose. The relationship between the metal concentration of residual copper ions in solution and the amounts of adsorbed copper ions by *P. acnes* was also investigated according to the Freundlich adsorption isotherm equation. The results obtained showed a linear relationship.

It has been observed that metal adsorption by microorganisms is largely dependent on the cell concentration at a given equilibrium concentration of mercury.

The adsorptions of copper ions by both the lyophilized and viable cells treated with or without heat were compared. The copper ion-adsorbing ability of the heat killed-cells was slightly less than that of the non-heated cells on viable *P. acnes* (Fig.2).

Also, the equilibration times for mercuric and copper ions with *P. acnes* were examined at pH 4.0. After the incubation of the microorganisms with the metal ions for 5 min, the adsorption rates of these metal ions by *P. acnes* reached a plateau.

These results suggest that there is no energy requirement for the adsorption of copper ions by *P. acnes* and that the accumulation of copper by the microorganisms depends on physico-chemical adsorption at the cell surface rather than on metabolic uptake.

The heavy metal-adsorbing abilities of the oral microorganisms have not been reported previously. The results obtained herein indicated that some species of oral microorganisms had high mercury and copper-adsorbing abilities.

It is recognized that dental plaque mainly consists of many kinds of oral microorganisms closely related to the etiology of dental caries and periodontal diseases. On the other hand, numerous oral microbes inhabit the oral cavity as well as endogenous microbes and matrix materials such as salivary components and carbohydrates.

Therefore, oral flora are also thought to disturb the establishment of exogenous microbes.

It may be assumed that the oral microflora may play some role as a barrier to protect exogenous origins in the oral eco-system. From the results obtained, as some oral microorganisms have high metal ion-adsorbing abilities, dental plaque may serve to eliminate heavy metal ions from the oral cavity.
