**Abstract:** The aim of this *in vitro* study was to determine the effect of violet-blue light on the metabolic activity of early *Streptococcus mutans* biofilm, reincubated at 0, 2, and 6 h after 5 min of violet-blue light treatment. *S. mutans* UA159 biofilm cells were cultured for 12 to 16 h in microtiter plates with Tryptic Soy broth (TSB) or TSB with 1% sucrose (TSBS) and irradiated with violet-blue light for 5 min. After irradiation, the plates were reincubated at 37°C for 0, 2, or 6 h in 5% CO₂. Colorimetric tetrazolium salt reduction assay was used to investigate bacterial metabolic activity. Mixed model ANOVA was used to find the difference between the violet-blue light treated and nontreated groups. Bacterial metabolic activity was significantly lower in the violet-blue light group for TSB than in the nontreated group (*P* < 0.0001) regardless of recovery time. However, the differences between metabolic activity in the treated groups without sucrose decreased over time. For TSBS, metabolic activity was significantly lower with violet-blue light at 0 and 2 h. Violet-blue light inhibited the metabolic activity of *S. mutans* biofilm cells in the light-treated group. This finding may present a unique treatment method for patients with active caries.

**Keywords** *Streptococcus mutans*; violet-blue light; biofilm; XTT assay.

**Introduction**

Oral biofilm, or dental plaque, composed of a group of microorganisms, is the primary cause of dental caries. Among them, *Streptococcus mutans* is a cariogenic bacterium with the ability to form a biofilm. Various preventive treatments are currently used and have been shown to reduce, inhibit, and even eliminate oral biofilm. Noninvasive phototherapy/photodynamic therapy is an alternative therapeutic approach currently studied in the treatment of microbial infections to prevent the emergence of antibiotic-resistant bacterial strains. It is also under study in various disciplines as wound healing, tissue regeneration (1,2), cancer therapy (3), and skin disorders (3,4) as well as in the prevention of caries and oral infections (5). This light therapy is widely applied to control biofilms with and without an exogenous photosensitizer (5-7). Although photodynamic therapy employing exogenous photosensitizers are widely studied to control oral biofilm, investigations related to photodynamic therapy using endogenous photosensitizers are developing rapidly (8,9).

Although visible light (380-700 nm) is commonly used to inhibit or kill bacteria (5,10), the reduction rate was statistically significant when treated with only blue light (400-500 nm; 10 min) (11). The synergistic effect of 20-s blue light treatment with hydrogen peroxide reduced the bacterial growth up to 96% (11). Whereas a delayed antibacterial effect (12,13) was reported by...
Feuerstein et al. (11) in an S. mutans biofilm grown for 6 h, whereas Chebath et al. (14) observed increased antibacterial effect after 3-, 5-, 7-, and 10-min treatment (13). Photoinactivation of S. mutans biofilm has been achieved through a 5-min treatment with violet-blue light with a peak wavelength of 405 nm (15). This study reported the effect of violet-blue light on biofilm formation, colony forming units, and growth kinetics of S. mutans. However, the effect of violet-blue light treatment on the metabolic activity of S. mutans biofilm has not been examined. Determining the metabolic activity of S. mutans will directly demonstrate the overall vitality of S. mutans after exposure to violet-blue light and indirectly assess the viability of the bacterial cells. Although we have quantified bacterial cell numbers after treatment with violet-blue light, the metabolic activity assay used provides a measure of the respiratory activity of the inactivated bacterial cells. Metabolic activities such as biological oxidation of sugars or carbohydrates are vital for the survival of S. mutans (16), including respiration and fermentation (Jurtshuk P Jr. Bacterial metabolism, Baron S ed, Medical Microbiology, Galveston, 1996), resulting in the generation of high energy compounds adenosine triphosphate (ATP) and adenosine diphosphate (ADP).

S. mutans, being a saccharolytic organism, uses heterotrophic metabolism to generate energy. End products such as lactic acid, acetate, formate, and ethanol are produced during bacterial fermentation of sugars. Enzymes such as various dehydrogenases are involved in S. mutans metabolism (Fig. 1). The chemical reactions in the metabolism of a bacterial cell are vital for the division, replication, viability, and growth of S. mutans (13). The aim of this in vitro study was to determine the effect of violet-blue light on metabolic activity using a 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide (XTT) reduction assay on pre-cultured S. mutans biofilm, which was reincubated for 0, 2, or 6 h after 5 min of violet-blue light treatment.

**Materials and Methods**

**Bacterial strain, media and culture conditions**

Bratthall serotype c strain S. mutans UA159 (ATCC 700610) obtained from American Type Culture Collection (Rockville, MD, USA) was used in this study. The strain was stored at −80°C in 20% glycerol and grown in mitis-salivaris sucrose bacitracin (MSSB, Anaerobe Systems, Morgan Hill, CA, USA) agar plates. Liquid broth cultures were prepared with 5 mL of tryptic soy broth (TSB, Acumedia, Baltimore, MD, USA) and incubated for 24 h in a 5% CO₂ incubator. S. mutans was grown in TSB without sucrose and in TSB supplemented with 1% sucrose (TSBS) as a biofilm in sterile 96-well flat bottom microtiter plates (Fisher Scientific, Co., Newark, DE, USA). The biofilm cells were incubated for 12 to 16 h in a 5% CO₂ incubator for the cells to reach the logarithmic phase of growth.

**Light source**

Quantitative light-induced fluorescence (QLF, Inspektor Research Systems, Amsterdam, The Netherlands), a caries-detection system was used in this study. The system is equipped with a 35-watt xenon arc lamp and a 370-nm blue light filter and has a spectral wavelength ranging from 380 to 450 nm and a peak excitation wavelength of 405 nm.

**Reagents**

"XTT (2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) sodium salt (Sigma-Aldrich, St. Louis, Missouri, USA) was used to detect metabolically active cells. Menadione (2-methyl-1, 4-naphthoquinone or vitamin K₃), an electron transporter, was used.
as an electron-coupling activator to reduce XTT to an orange-colored Tetrazolium Red Formazan (1-phenyl-2-[phenyl(2-phenylhydrazinylidene) methyl] diazene) in metabolically active cells.

**Colorimetric tetrazolium assay for metabolic activity**

*S. mutans* was grown in 200 µL of either TSB or TSBS by pipetting 190 µL of TSB or TSBS and 10 µL of an overnight culture into each well. *S. mutans* biofilm cells were grown in 96-well microtiter plates with a 1-well gap between the samples so that the light targeting a given well does not impact surrounding wells. Before irradiation with violet-blue light, the supernatant or planktonic medium was removed. The wet biofilm was continuously irradiated with violet-blue light for 5 min at a fixed distance of 2 cm from the biofilm. After irradiation, 0.9% saline was added to the wells and the plates were either not reincubated or reincubated for 2 or 6 h after addition of TSB and TSBS, respectively. The metabolic activity of the treated biofilm cells was determined using an adaptation (17) of the method developed originally by Pierce et al. (18). XTT sodium salt solution was freshly prepared and activated with menadione. The *S. mutans* biofilm cells were gently washed twice with 0.9% saline, then 200 µL of the XTT solution was added, covered with aluminum foil, and incubated for 2 h in a dark environment at 37°C. The supernatant was removed and pipetted into another 96-well microtiter plate and measured for absorbance at 490 nm.

**Statistical analysis**

The metabolic activity determined by the XTT assay and the effect of violet-blue light on *S. mutans* and the nontreated control group based on various recovery time periods of 0, 2, and 6 h were analyzed separately based on the growth medium without sucrose (TSB) and with 1% sucrose (TSBS) using mixed-model ANOVA, which included fixed effects for the treated and nontreated groups of violet-blue light, time periods of reincubation, and effect of light-by-time-period interaction and a random effect for each experiment. Pair-wise comparisons were made using Fisher’s protected least-significant differences to control the significance level at 5%. Analyses were performed on the log-transformed data.

**Results**

The effect of light with respect to recovery time was significant both in the absence (TSB) and in the presence of sucrose (TSBS; *P* < 0.0001). The metabolic activity of TSB-grown *S. mutans* cells treated with violet-blue light was significantly lower than the nontreated group regardless of the recovery time (*P* < 0.0001; 0 h, Fig. 2; 2 h, Fig. 3; and 6 h, Fig. 4). The decreasing differences between XTT and with and without light show that the effect of violet-blue light decreased as recovery time increased. The metabolic activity was significantly decreased at 0 h compared with a 2-h (*P* = 0.0021; Fig. 3) and a 6-h recovery period (*P* = 0.0012; Fig. 4). The metabolic activity was not significantly different from each other (*P* = 0.90) after the 2-h and 6-h recovery periods.

The metabolic activity of TSBS-grown *S. mutans*...
treated with violet-blue light was significantly lower ($P < 0.0001$) than the nontreated control group (Fig. 2) at recovery periods of 0 h and 2 h ($P < 0.0001$; Fig. 3). However, the difference was not significant at the 6-h recovery period ($P = 0.30$; Fig. 4). For TSBS-grown *S. mutans*, regardless of light treatment, there was no significant effect due to recovery time ($P = 0.66$).

**Discussion**

In our previous study, we demonstrated photoinactivation of *S. mutans* with 5 min of violet-blue light treatment by quantitatively determining the viability (colony-forming units) of biofilm cells (15). In this study, we found decreased metabolic activity of violet-blue light-treated *S. mutans* at 0-h and 2-h recovery periods, providing an indirect estimation of cell viability. The metabolic activity of TSBS *S. mutans* remained unaffected after 6-h recovery period and was increased compared with 0-h recovery period. We previously reported that there was no difference in biofilm formation with respect to light treatment after the 6-h reincubation period in the TSBS group, which suggests that the bacterial cells are viable (15). Bacterial cells, however, which are encompassed within extracellular glucans, may be improperly reduced by tetrazolium salts (19) in the assay used in this study. This suggests the significant reduction of bacterial cells in TSB compared with TSBS as the microcolonies protect *S. mutans* from violet-blue light. The respiring bacterial cells produce NADH, and the hydrogen ions are accepted by tetrazolium salt (XTT), which is further converted to a colored formazan compound (20). Compared with 0 h, both 2- and 6-h recovery periods produced increased metabolic activity. The biofilm formed at baseline of 0 h became viable at 2 and 6 h, and the biofilm formed correlated with the time of reincubation. The violet-blue light-treated groups, however, produced reduced metabolic activity compared with the nontreated group.

There was some impairment in the chemical reactions responsible for metabolizing carbohydrate sources after violet-blue light treatment contributing to the inhibition of metabolic activities in *S. mutans* biofilm cells seen in this study. The pathogenic nature of cariogenic biofilm is determined by metabolic activity (21). Dehydrogenases in bacterial cells play a vital role in metabolic activities. Hydrogen ions from NADPH are accepted by artificial electron transporting reagents such as menadione, and the electrons are transferred to the resulting tetrazolium salt. The colorless XTT compound can enter bacterial cells through intact cell walls and membranes through a redox process and be converted into orange formazan derivatives. Formazan, formed in the culture supernatant, is a water-soluble compound, and can be measured by absorbance measurements. Quantification of bacterial cell number and correlation with the colored signal may be a better option. However, photoactivated bacterial cells that are not viable, but metabolically active, cannot be determined through colony counting. The efficacy of violet-blue light through use of a colorimetric method for assessing the metabolic activity helps to design future studies such as determining the expression of virulence factors associated with biofilm formation and the efficacy of violet-blue light on *S. mutans* biofilm grown on human enamel or dentin specimens.

Five minutes of irradiation time is longer than that for at-home procedures. Irradiation could be done as a part of prophylactic treatment in a dental clinic; however, patient noncompliance with the at-home procedure could be a potential disadvantage. Determination of the minimum irradiation time necessary to inhibit *S. mutans* biofilm formation should be conducted in future studies. This will potentially help to reduce the irradiation time in minutes. Effectiveness of blue light after 20, 30, and 60 s cannot be achieved with only violet-blue light, as seen in the presence of exogenous photosensitizers. There is also recovery of biofilm after 2 and 6 h, suggesting that repeated treatments may be necessary to prevent the regrowth of biofilm. Within the limitations of this study, more innovative approaches are needed.

The metabolic activity of *S. mutans* was significantly lower ($P < 0.0001$) than the nontreated control group (Fig. 2) at recovery periods of 0 h and 2 h ($P < 0.0001$; Fig. 3). However, the difference was not significant at the 6-h recovery period ($P = 0.30$; Fig. 4). For TSBS-grown *S. mutans*, regardless of light treatment, there was no significant effect due to recovery time ($P = 0.66$).
reduced in the violet-blue light-treated group compared with the nontreated group immediately after treatment. However, there was some recovery of the biofilm cells after treatment with violet-blue light. Although the bacterial cells were inactivated immediately, the respiratory capacity of the bacteria was not affected after 6 h of treatment in the presence of sucrose, suggesting that repeated violet-blue light treatment is highly recommended for the prevention and control of oral biofilms to prevent dental caries. Violet-blue light at home and in clinical settings could serve as an adjunct prophylactic treatment in controlling the bacterial numbers based on its significant inhibitory effect for a longer period in the absence of sucrose.
