(Received 3 March and accepted 4 September 2000)

Abstract: We conducted a 3-year follow-up study of 2,008 individuals for the persistence of antibody levels after vaccination with a recombinant hepatitis B vaccine. At 1 month after vaccination had been completed 96.3 % of subjects had acquired protective HB surface (HBs) antibody titers on passive hemagglutination assay (PHA) of 23, and 3 years after completion of the vaccination 63.1 % had acquired similar titers. The titer decreased below this level after 3 years in 34.5 % of subjects who had initially acquired protective antibody titers. The mean acquired HBs antibody titer on PHA was 25.8 at 1 month and 23.1 at 3 years after completion of the vaccination. The regression line for these changes was expressed as logY = 1.800 - 0.24X by the least squares method. The antibody level was estimated to decrease to 2 at 37 months and to seronegativity at 75 months. On the basis of the relationship between PHA antibody titers and the period of their persistence, the persistence of antibody levels after vaccination with a recombinant vaccine can be estimated from the acquired antibody titer determined 1 month after completion of the vaccination, as with plasma-derived vaccines. (J. Oral Sci. 42, 147-150, 2000)

Key words: recombinant HB vaccine; persistence of HBs antibody levels; follow-up study.

Introduction

It is not rare for dental care providers to come into contact with patients' blood in clinical practice. Therefore, protection against infectious diseases that can be mediated by blood, such as hepatitis B virus (HBV) infection, is a critical issue in dental practice. A useful strategy for prevention of these infections is to increase the resistance of the host, particularly by vaccination. Prevention of HBV infection by hepatitis B (HB) vaccination has been practiced for nearly 15 years. The vaccines in use were plasma-derived vaccines in the initial stage, but yeast-derived recombinant HB vaccines are currently predominant. Data on the rate of acquisition of antibodies and their diminution after vaccination with a recombinant HB vaccine based on detailed surveys and studies are lacking at present, in contrast with data on plasma-derived vaccines (1).

In particular, little has been reported on decreases in acquired antibodies after vaccination (2,3), and the pattern of decrease in acquired resistance after vaccination with a plasma-derived vaccine has been used as a surrogate. The key issue in vaccination in a high-risk group is the maintenance of acquired antibodies at levels high enough to prevent infection. However, currently there is no routine follow-up monitoring of antibody levels, and the pattern of decreases in acquired antibodies after vaccination with a recombinant HBV vaccine remains unclear.

Therefore, individuals may lose resistance to HBV after vaccination, even though they think that they are protected. In this connection, the present study was designed to determine the optimal interval for vaccination with a
recombinant HBV vaccine, the standard method of immunization, for achieving effective protection against HBV infection.

**Subjects and Methods**

The subjects were those who were negative for HBs antigen and antibody and had normal levels of glutamic oxaloacetic transaminase (GOT) and glutamic pyruvic transaminase (GPT) screened from among 2,158 persons who were engaged in high-risk occupations. Data from 2,008, who were examined for HBs antibody 1 month and 3 years after completion of the vaccination series were analyzed. The numbers of people vaccinated at respective stages of the study are shown in Fig. 1.

The mean age of the subjects was 34.8 ± 9.3 years. The vaccine used was Chinese hamster ovary-derived recombinant precipitating HB vaccine (γ-HB vaccine, Mitsubishi).

According to the following method, the subjects were given two inoculations of 10 μg with a 1-month interval, followed by booster immunization given 6 months later. The levels of HBs antibody in the vaccines were determined 1 month and 3 years after the third inoculation. The levels of HBs antibody were determined 1 month and 3 years after completion of the vaccination series were analyzed on the basis of the results of simultaneous assays. A regression line for these changes was calculated using SPSS 10.0J for Windows (SPSS Japan) or the least squares method (5), after transformation into a logarithm scale.

---

**Results**

The percentage of subjects with positive HBs antibody titers was 98.4 % (n = 1,476) at 1 month and 80.3 % (n = 1,613) at 3 years. Table 1 shows the breakdown of vaccinations in relation to the antibody titer. The percentage of subjects who had positive PHA titers of 2³ or more was 96.3 % (n = 1,933) at 1 month and 63.1 % (n = 1,266) at 3 years. Changes in the HBs antibody titer over 3 years were analyzed according to high-, intermediate-, and low-response groups of subjects classified in terms of the PHA titer (2³, 2²-2¹, 2¹) obtained 1 month after completion of the vaccination (Table 2). In the high-response group, those who had an initial postvaccination antibody titer of 2³ or more showed a decrease in the mean antibody titer to 2³ at 3 years and those who had an initial postvaccination antibody titer of 2¹ showed a decrease to 2² at 3 years. In the intermediate-response group, subjects who had initial antibody titers of 2² and 2¹, the mean antibody titer decreased to 2¹ and 2² respectively at 3 years.

In the low-response group the antibody titer decreased from 2¹ initially to 2². The regression line for these changes was obtained by the least squares method. The time (months) until the HBs antibody titer would decrease to 2² or to seronegativity was estimated from the obtained regression line (Table 3). The gradient of changes in the antibody titer was similar in the high- and intermediate-response groups, whereas the low-response group showed a slightly less steep slope. On average, the changes in the antibody titer followed a regression line expressed as log Y = 1.800 - 0.024X. The time the antibody titer would take to reach 2² was estimated to be 62 months, 33 months, 23 months, and 14 months after completion of the vaccination.

in the subjects who had initial postvaccination antibody titers of 2⁺ or more, 2⁺, 2⁺, and 2⁺, respectively. In the group as a whole, the antibody titer was estimated to decrease to 2⁺ at 37 months and to seronegativity at 75 months.

**Discussion**

Prevention of type B hepatitis by means of HB vaccination has been practiced for more than 10 years, and its great contribution to protection of infants from becoming carriers through mother-to-child transmission has been recognized (6).

However, there have been few reports on prevention of nosocomial infection by horizontal transmission. The available study of this kind was Rosen et al. (7), who examined long-term study of infections among hospital employees. According to Hadler et al. (8), the estimated protective level of HBS antibody against HB virus is 10 mIU/ml, which corresponds to an antibody titer of 2⁺ by PHA. A survey of accidental HB virus infections pointed out that, in fact, the boundary between developing and resisting the infectious disease was a PHA titer of 2⁺ in the host. Taking this finding into account, the percentage of subjects who acquired protective levels of antibodies with the recombinant HB vaccine should be regarded as 96.3 % at 1 month and 63.1 % at 3 years, rather than 98.1 % at 1 month and 80.3 % at 3 years.

Nevertheless, these percentages are about 20 % higher than the corresponding figures reported for plasma-derived vaccines. Changes in antibody levels in the subjects of our study high-, intermediate- and low-response groups classified in terms of the antibody titer obtained 1 month after completion of the vaccination (Fig. 2).

Although our results were expressed as straight lines because there were only two measuring points, it is apparent that the decreasing is similar for the result from plasma-devised vaccine, reported by Robert et al. (9) and our study of vaccine. It is possible to estimate the persistence of antibody levels on the basis of the antibody titer determined 1

month after completion of the vaccination. According to the regression line obtained in our study, the HBs antibody titer seems to decrease to $2^2$ after 1-2 years in subjects with an initial PHA titer of $2^4$ or $2^5$, and after 3-5 years in those with an initial PHA titer of $2^6$ or higher. On average, the acquired antibody level is estimated to reach $2^3$ at 37 months and seronegativity at 75 months. These figures were very close to the results for a Merck recombinant vaccine reported by lino et al. (3); they observed that HBs antibody decreased to a level of 10 mIU/ml at 37 months and to seronegativity at 77 months. Therefore, it is reasonable to conclude that the pattern of decreases in the antibody titer after vaccination with a recombinant vaccine is similar to that with a plasma-derived vaccine. The results of the present study showed that the HBs antibody titer would decrease to $1/2^3$ in 3 years, with an annual decrease of about $1/2$. Figure 3 is a schematic diagram of such a decrease in relation to the initially acquired antibody level.

If booster immunization is given by the time the PHA titer reaches $2^3$ in this schema, the protective antibody level can be maintained. For this purpose, the minimum requirement for effective prevention of HB infection is that each person vaccinated be aware of his or her own acquired level of antibodies by undergoing measurement of the antibody level after vaccination.
