**Abstract.** This study investigated the effects of alcoholic extract of *Butea superba* (BS) on cognitive deficits and depression-related behavior using olfactory bulbectomized (OBX) mice and the underlying molecular mechanisms of its actions. OBX mice were treated daily with BS (100 and 300 mg/kg, p.o.) or reference drugs, tacrine (2.5 mg/kg, i.p.) and imipramine (10 mg/kg, i.p.) from day 3 after OBX. OBX impaired non-spatial and spatial cognitive performances, which were elucidated by the novel object recognition test and modified Y maze test, respectively. These deficits were attenuated by tacrine and BS but not imipramine. OBX animals exhibited depression-like behavior in the tail suspension test in a manner reversible by imipramine and BS but not tacrine. OBX down-regulated phosphorylation of synaptic plasticity–related signaling proteins: NMDA receptor, AMPA receptor, calmodulin-dependent kinase II, and cyclic AMP-responsive element-binding protein. OBX also reduced choline acetyltransferase in the hippocampus. BS and tacrine reversed these neurochemical alterations. Moreover, BS inhibited *ex vivo* activity of acetylcholinesterase in the brain. These results indicate that BS ameliorates not only cognition dysfunction via normalizing synaptic plasticity–related signaling and facilitating central cholinergic systems but also depression-like behavior via a mechanism differing from that implicated in BS amelioration of cognitive function in OBX animals.

**Introduction**

*Butea superba* (BS) (Red Kwao Kua in Thai) is an herb in the family Papilionaceae (Leguminosae) which is abundantly distributed in Thai deciduous forests. The tuberous roots of this plant have long been taken as a folk medicine not only to increase physical and mental strength but also to prevent aging-related symptoms such as impaired sexual performance in middle-aged or elderly males (1, 2). Evidence from a randomized double-blind clinical trial (3) showed that oral administration of powdered tubers of this plant to patients with erectile dysfunction (ED), aged 30 to 70 years, caused noticeable improvement without apparent toxicity. In fact, this clinical finding was supported by pharmacological (2) and chemical studies of this plant (4), demonstrating that BS enhances penile erection in rats and that some isoflavonolignans such as butesuperin A and B are chemical constituents with inhibitory activities against phosphodiesterase type 3A and type 5, enzymes targeted for ED therapy. Its ethno-medical uses and chemical constituents suggest that BS may have potential for the treatment of neurocognitive and/or neuropsychiatric symptoms.
Alzheimer’s disease (AD) is a progressive neuro-degenerative disorder that is characterized by memory dysfunction and behavioral and psychological symptoms of dementia (BPSD), including depression. An increasing population of AD patients is a serious social and economic problem in super-aging societies worldwide (5). Current approved treatment with anti-dementia drugs such as donepezil, an acetylcholinesterase inhibitors, and memantine, an N-methyl-d-aspartate receptor (NMDA) antagonist, has provided marginal therapeutic benefits without affecting the progression of the disease (6). Therefore, new drug discovery and the establishment of new therapeutic methods are greatly needed.

Olfactory bulbectomy (OBX) in rodents has been widely used as an animal model to investigate emotional dysfunction such as depression (7 – 10). Indeed, OBX causes depression-like behavioral and neurochemical alterations in rodents that are susceptible to antidepressant treatment (11 – 13). Moreover, OBX has been used as one of the AD models since impairment of olfactory perceptual acuity is observed not only at the early stage of AD (14, 15) but also in a transgenic AD model of mice over-expressing a mutant form of the human amyloid-β-precursor protein (16). In addition, OBX causes elevation of the Aβ level in the brain (17) and the degeneration of septo-hippocampal cholinergic system in rodents (8, 9, 18), and thereby induces cognitive dysfunction (8 – 10).

In this study, we elucidated the anti-dementia and antidepressant drug-like effects of BS and the mechanism underlying its action using an OBX model mouse to obtain a better understanding of the potential availability of BS for the treatment of cognitive and emotional dysfunction. The present findings clearly demonstrated that BS ameliorates cognitive and depression-like emotional deficits of OBX mice and that the effects on the cognitive deficits are mediated in part by normalization of OBX-induced dysfunction of neuroplasticity-related neuronal signaling and cholinergic systems. Our findings suggested that BS is useful for the treatment of AD patients with depressive symptoms.

Materials and Methods

Animals

This study was conducted according to the experimental protocols as described in Fig. 1. A total of 85 male ddY mice were obtained at the age of 8 weeks (Japan SLC, Inc., Shizuoka). The animals were habituated to the laboratory animal room for at least 1 week before surgery. Food and water were available ad libitum. Housing was thermostatically maintained at 24°C ± 1°C with constant humidity (65%) and a 12-h light-dark cycle (lights on: 07:00 – 19:00). The behavioral experiments were performed during the light phase from 9:00 to 18:00. The present studies were conducted in accordance with the Guiding Principles (NIH publication #85-23, revised in 1985) for the Care and Use of Animals and were approved by the Institutional Animal Use and Care Committee of the University of Toyama.

Preparation of plant extract

The ethanol extract of BS was prepared as previously described. Briefly, the root of BS was collected in Lampang Province in Thailand in 2011 and identified by Dr. Chaiyo Chaichantipyuth (Department of Pharmacognosy, Faculty of Pharmaceutical Sciences, Chulalongkorn University, Thailand). The dried powder of the root (52 g) was extracted with 200 ml of 95% ethanol at 75°C for 2 h and filtrated. This step was repeated 3 times; and the filtrated samples were combined, concentrated under reduced pressure at 40°C, and then dried in vacuo. The yield of the extraction from the dried root was calculated.

![Fig. 1. Schematic drawing of experimental protocol. ddY mice received daily administration of Butea superba extract (BS; 100 – 300 mg/kg, p.o.), tacrine (THA; 2.5 mg/kg per day, i.p.), imipramine (IMP; 10 mg/kg per day, i.p.) or tap water from day 3 after the operation. The administration was repeated during the experimental period. Each experiment was conducted at 1 – 2-week interval as described in the text. After completing the behavioral experiments, the mice were decapitated under pentobarbital anesthesia. The brain tissues were used for neurochemical studies.](image-url)
as 8.9% (w/w). The BS (voucher specimen No. TMPW-27997) and its extract (voucher specimen no INM-531) used in this study were deposited at our institute.

LC–MS analyses were also performed with a Shimadzu LC-IT-TOF mass spectrometer equipped with an ESI interface. The ESI parameters were as follows: source voltage, +4.5 kV; capillary temperature, 200°C; and nebulizer gas, 1.5 l/min. The mass spectrometer was operated in positive ion mode scanning from m/z 200 to 2000. A Waters Atlantis T3 column (2.1 mm i.d. × 150 mm) was used and the column temperature was maintained at 40°C. The mobile phase was a binary eluent of A) 5 mM ammonium acetate solution and B) acetonitrile under the following gradient conditions: 0 – 30 min, linear gradient from 10% to 100% B and 30 – 40 min, isocratic at 100% B. The flow rate was 0.2 ml/min. Mass spectrometry data obtained from the extract have been listed in the MassBank database (19) and stored together with the pharmacological information on the extract in the Wakan-Yaku DataBase system (http://wakandb.u-toyama.ac.jp/wiki/LCMS:Butea_INM-531), Institute of Natural Medicine, University of Toyama.

Surgical operation

OBX of mice was conducted on day 0 as previously described (8 – 10). The mice were anesthetized with sodium pentobarbital (60 mg/kg, i.p.) and fixed on stereotactic instruments (Narishige, Tokyo). With 1% lidocaine solution used as a local anesthetic, the skull covering the bulbs was exposed by skin incision, and then a 1-mm burr hole was drilled. The bilateral bulbs were aspirated through a syringe and the cavity of the bulbs was filled with a hemostatic gelatin sponge. After completing the behavioral studies, all the animals were sacrificed and the operated lesion was verified visually. The data from animals with less than 70% removal or with no intact cortex were excluded from the data analysis. The success rate of surgical operation was 98% (49/50). Sham operation was performed in a similar way without removal of the bulb. At the end of the experiments, the olfactory bulbs of the sham-group mice were also confirmed to be intact.

Drug administration

Either vehicle water or test drugs were administered daily from day 3 after surgery during the experimental period. On the behavioral testing day, administration was conducted 1 h before the testing. Sham-group mice and OBX-control group mice were perorally administered water. Tacrine (9-amino-1,2,3,4-tetrahydro-acridine HCl) and imipramine HCl (Sigma-Aldrich Co., St. Louis, MO, USA), reference standard drugs, were dissolved in 0.9% saline and administered once daily at doses of 2.5 and 10 mg/kg (i.p.), respectively. BS extract was suspended in water and given perorally at daily doses equivalent to 100 and 300 mg (dried herb weight)/kg. The daily doses of BS used in the present animal experiments were almost 10 – 30 times more than that used for human ED therapy (3).

Behavioral study

The following behavioral experiments were started from 2 weeks after surgery.

Novel object recognition test (ORT)

ORT was conducted at days 17 – 20. This test is based on the tendency of mice to discriminate a familiar from a new object. This test was conducted as previously described (8, 9, 20) with minor modification. Briefly, mice were individually habituated to an observation box (50 × 50 × 40 cm) for 10 min on the day before the experiment. The ORT consisted of a sample phase trial and a test phase trial. In the sample phase trial, each mouse was placed in the observation box where two identical objects, object 1 and object 2, were placed separately, and allowed to explore the area freely for 5 min. The total time that the mouse spent exploring each of the two objects was measured and then the mouse was returned to the home cage. In the test phase trial performed 30 min after the sample phase trial, one of the two objects was replaced by an identical copy (familiar object) and the other by a novel object. Performance of the animals in this test was video-recorded for later analysis. In these trials, the exploration of an object was defined as directing the nose to the object at a distance of < 2 cm according to previous reports (8, 9, 20) and the time spent exploring each of the two objects was analyzed using SMARTW ver. 2.5 (PanLab, S.L., Barcelona, Spain) with a tri-wise module to detect the head, center mass, and base tail.

Modified Y-maze test

A modified version of the Y-maze test was conducted at days 24 – 27 according to Yamada et al. (9). The apparatus used for this test consists of black polypropylene walls with 3 arms, each 40-cm-long, 12-cm-wide at the top, 3-cm-wide at the bottom, and 18-cm-high. This test was a two-trial task with a sample phase trial and a test phase trial that were separated by an inter-trial interval. In the sample phase trial, each mouse was individually placed in the maze with one of the 3 arms closed. The animal was allowed to explore the other 2 arms freely for 5 min. Thirty minutes after the sample phase trial, the animal was again placed in the maze with all 3 arms opened, and allowed to explore the arms...
freely. The previously closed arm that was opened in the test phase trial was defined as the new arm. The animal behavior was video-recorded for later analysis. Percent time spent in the new arm was analyzed using SMART® system ver. 2.5 (PanLab).

**Tail suspension test (TST)**

We employed TST to assess the antidepressant effects of the test drugs (21). This test was conducted at days 38 – 40 as previously described (10). Briefly, mice were subjected to the short-term inescapable stress of being suspended by the tail, which leads to the development of an immobile posture. The animals were separately suspended 50 cm above the floor in a chamber by adhesive tape placed approximately 2 cm from the tip of the tail. The animal behavior in the test was video-recorded for later analysis. Immobility was defined as a state with movement speed no more than 0.05 cm/s using SMART® system ver. 2.5; immobility time was recorded for 8 min and the performance during the last 6-min period was analyzed.

**Neurochemical study**

One week after completing the behavioral experiments, mice were decapitated under pentobarbital (50 mg/kg, i.p.) anesthesia. The hippocampal tissues were quickly dissected out and stored at −80°C until use.

**Western blotting**

Expression of synaptic plasticity–related proteins in the hippocampus was analyzed using western blotting as previously described (8, 22, 23). The following primary antibodies were used: anti-NMDAR1 rabbit polyclonal antibody (1:1000 dilution), anti-phospho-NMDAR1 (p-NMDAR1) (pSer896) rabbit polyclonal antibody (1:1000 dilution) (Cell Signaling Technology, Danvers, MA, USA); anti-glutamate receptor 1 (GluR1) (p-GluR1) (p-Ser831) rabbit polyclonal antibody (1:1000 dilution) (Cell Signaling Technology), anti-CaMKIIα (A-1: sc-13141) mouse monoclonal antibody (1:1000 dilution), anti-phospho-CaMKII (p-CaMKII) (pThr286) rabbit polyclonal antibody (1:1000 dilution), anti-CREB (48H2) rabbit monoclonal antibody (1:1000 dilution), anti-phospho-CREB (p-CREB) (pSer133) rabbit monoclonal antibody (1:1000 dilution), anti-choline acetyltransferase (ChAT) goat polyclonal antibody (1:5000 dilution) (AB-144P; Millipore, Temecula, CA, USA); and anti-β-actin mouse monoclonal antibody (1:10,000 dilution, Abcam®, Cambridge, UK). The immune complexes were detected by the enhanced chemiluminescence method (ImmobilonTM Western Chemiluminescent HRP Substrate) (Millipore) and imaged using Lumino Image Analyzer LAS-4000R (Fuji Film, Tokyo). The quantity of immune-reactive bands was analyzed using ImageQuant TL software (GE Healthcare, Buckinghamshire, UK). The quantity of immunoreactive bands was normalized by comparison with their expression levels in treatment-naive control mice. The expression levels of each target protein were reprobed using a Blot Restore Membrane Rejuvenation Kit (Millipore).

**Ex vivo measurements of acetylcholinesterase (AChE) activity in the brain**

Ex vivo AChE activity in the cerebral cortex was determined by the colorimetric method as previously described (8 – 10, 24). Briefly, 9-week-old male mice received daily administration of 300 mg/kg BM for 14 days. The animals were decapitated 1 h after the last administration and the cerebral cortices were dissected out from the brain. The frozen cortex was weighed and homogenized in 10 volumes of 0.1 M phosphate buffer (pH 7.4) containing 1% Triton-X-100. After centrifugation at 15,000 × g and 4°C for 20 min, the clear supernatants were collected and served as the enzyme source. Cholinesterase activity was determined in 50 µl aliquots of homogenates (run as duplicates) in a 96-well flat-bottomed microplate. The reaction was started by adding 20 µl of 10 mM 5,5′-dithiobis-2-nitrobenzoic acid (DTNB), 20 µl of 7.5 mM acetylthiocholine (ATCI), and 160 µl of 0.1 M sodium phosphate buffer (pH 8.0). The spectrophotometric absorption at 405 nm during a 5-min incubation period at 25°C was quantitatively measured using a microplate reader (Sunrise Classic; TECAN Japan, Kawasaki) and is expressed as nmol ACh hydrolyzed/min per mg tissue.

**Data analyses**

The data are expressed as the mean ± S.E.M. The data obtained from the object recognition test were analyzed by the paired Student’s t-test and the data obtained from other behavioral and neurochemical experiments were analyzed by one-way analysis of variance (ANOVA) followed by a post hoc multiple comparison test (Student-Newman-Keuls method) as appropriate. Differences of \( P < 0.05 \) were considered significant. The analysis was conducted using SigmaStat® ver. 3.5 (SYSTAT Software Inc., Richmond, CA, USA).

**Results**

**BS attenuates OBX-induced non spatial short-term memory deficits in the object recognition test**

The object recognition test was used to evaluate the effects of BS on the non-spatial cognitive memory of OBX mice (25). In the sample phase trials, none of the
animal groups showed significant differences in time spent exploring each identical object. In the test phase trial, the sham group spent a significantly longer time exploring the novel object than exploring the familiar one ($t = -10.500$, $df = 18$, $P < 0.001$), while the vehicle-treated OBX group showed no preference for the novel object ($t = 1.521$, $df = 18$, $P = 0.163$). BS (300 mg/kg per day)- and tacrine-treated OBX mice, as well as the sham group, spent a significantly longer time exploring the novel object than the familiar one. (BS-treated OBX group: $t = -2.843$, $df = 18$, $P = 0.019$; tacrine-treated OBX group: $t = -5.525$, $df = 18$, $P < 0.001$) (Fig. 2). In contrast, BS (100 mg/kg per day)- and imipramine-treated OBX mice did not show a preference for the novel object.

**BS treatment reverses spatial short-term memory deficits of OBX mice in the modified Y-maze test**

We also examined the effect of BS treatment on time visiting the novel arm in the modified Y-maze test. As shown in Fig. 3, the ratio of the time that the sham group spent visiting the novel arm to the time spent visiting the other two familiar arms was higher than the chance level of 33.3%, indicating a preference for the novel arm over the familiar arms. The vehicle-treated OBX mice spent a significantly shorter time exploring the novel arm than the sham mice [one-way ANOVA: $F(5,50) = 8.420$, $P < 0.001$].

**Fig. 3.** Effects of BS and tacrine (THA) on OBX-induced spatial working memory deficit. A: Experimental protocols depicting the modified Y-maze test. The maze was surrounded by different spatial cues. The sample and test trials were conducted for 5 min at a 30-min interval. In the sample trial, each mouse was individually placed in the maze with one of the 3 arms closed. The previously closed arm that was opened in the test trial was defined as the novel arm. Results are expressed as % time animals spent exploring the novel arm in the test trial. B: Spatial short-term working memory performance of sham and OBX groups in the test trials conducted after 30 min. Each data column represents the mean ± S.E.M. (n = 9 – 12). ***$P < 0.001$ vs. vehicle-treated OBX group (post hoc Student-Newman-Keuls test).
BS reversed OBX-induced downregulation of glutamatergic neural plasticity in the hippocampus

To understand the molecular mechanisms underlying BS-induced improvement of cognitive deficits in OBX mice, we examined the effects of BS on the synaptic plasticity–related neuro-signaling pathway in the hippocampus of OBX mice by western blotting. No differences in the hippocampal NMDAR1 (NMDAR subunit), GluR1 (AMPA receptor subunit), CaMKIIα, and CREB levels were found among OBX, BS, or reference drugs (Fig. 5). The expression levels of phosphorylated NMDAR1, GluR1, CaMKIIα, and CREB in the OBX mice were significantly decreased compared with the levels in the sham mice. However compared with vehicle-treated sham mice, vehicle-treated OBX mice showed a significant decrease in the levels of pSer896-NMDAR1 [one-way ANOVA: F(4,15) = 3.505, P = 0.033; post hoc test: sham vs. vehicle-treated OBX group, P = 0.039], pSer831-GluR1 [one-way ANOVA: F(4,15) = 5.863, P = 0.005; post hoc test: sham vs. vehicle-treated OBX group, P = 0.041], pThr286-CaMKII [one-way ANOVA: F(4,15) = 4.725, P = 0.011; post hoc test: sham vs. vehicle-treated OBX group, P = 0.010], and pSer133-CREB [one-way ANOVA: F(4,15) = 4.270, P = 0.017; post hoc test: sham vs. vehicle-treated OBX group, P = 0.032]. BS and tacrine treatment ameliorated OBX-induced downregulation of pSer896-NMDAR1 [post hoc test: vehicle-treated OBX group vs. BS-treated OBX group, P = 0.042; vehicle-treated OBX group vs. tacrine-treated OBX group, P = 0.036] and pSer831-GluR1 [post hoc test: vehicle-treated OBX vs. BS (300 mg/kg per day)-treated OBX, P = 0.046; vehicle-treated OBX vs. tacrine-treated OBX, P = 0.021] and pSer133-CREB [post hoc test: vehicle-treated OBX group vs. BS (300 mg/kg per day)-treated OBX group, P = 0.025; vehicle-treated OBX group vs. tacrine-treated OBX group, P = 0.011] and pThr286-CaMKII [post hoc test: vehicle-treated OBX vs. BS (300 mg/kg per day)-treated OBX, P = 0.017; vehicle-treated OBX vs. tacrine-treated OBX, P = 0.012] (Fig. 5: B – E). Imipramine treatment significantly reversed OBX-induced down-regulation of pThr286-CaMKII [post hoc test: vehicle-treated OBX vs. imipramine-treated OBX, P = 0.028] and pSer133-CREB [post hoc test: vehicle-treated OBX vs. imipramine-treated OBX, P = 0.043], but it had no effect on pSer896-NMDAR1 [post hoc test: vehicle-treated OBX vs. imipramine-treated OBX, P = 0.103], pSer831-GluR1 [post hoc test: vehicle-treated OBX vs. imipramine-treated OBX, P = 0.502].

BS facilitated central cholinergic systems in the brain of OBX mice

The expression of ChAT, a cholinergic marker in the
Anti-dementia Effects of *Butea superba*

The hippocampus, was examined by western blotting. Compared with that in the sham-operated group, the vehicle-treated OBX group exhibited a reduced expression level of ChAT in the hippocampus [one-way ANOVA: F(4,15) = 11.080, P < 0.001; post hoc test: sham vs. vehicle-treated OBX, P = 0.007]. OBX-induced down-regulation of ChAT expression was reversed by BS and tacrine but not by imipramine [post hoc test: vehicle-treated OBX group vs. BS (300 mg/kg per day)-treated OBX group, P = 0.005; vehicle-treated OBX group vs. tacrine-treated OBX group, P < 0.001; vehicle-treated OBX group vs. imipramine-treated OBX group, P = 0.087] (Fig. 6).

The effect of tacrine and BS on ex vivo AChE activity in the brain

We analyzed the effect of BS on ex vivo activities of AChE in the brain to examine the possible involvement of endogenous acetylcholine in the action of BS. As shown in Fig. 7, importantly, the activity of cortical AChE in the mice treated with BS and tacrine for 2 weeks was significantly lower than that in the vehicle-treated mice [one-way ANOVA: F(2,19) = 8.129, P = 0.003; post hoc test: vehicle-treated group vs. BS-treated group, P = 0.016; vehicle-treated group vs. tacrine-treated group, P = 0.002].

Discussion

In this study, we investigated the effects of BS on OBX-induced cognitive deficits and depression-like behavior. The present findings demonstrated that BS administration ameliorates not only cognitive deficits but also depression-like behavior in OBX animals and suggested that the anti-dementia effect is at least in part due to restoring synaptic plasticity–related signaling and enhancement of cholinergic systems via inhibiting the activity of AChE in the brain.
We first employed an object recognition test to elucidate short-term non-spatial working memory (26). Working memory is one of the types of short-term memory that have been reported to be impaired at an early stage in patients with AD (27). In the sample trial of this test, no significant difference in total time spent exploring two identical objects was observed between sham and OBX groups, indicating virtually no differences in the ability to recognize objects between animals.

In the test trial, sham-operated mice spent more time exploring a novel object, while vehicle-treated OBX mice failed to discriminate between familiar and novel objects, indicating impairment of non-spatial working memory. The result that OBX-induced impairment of object recognition performance was reversed by the AChE inhibitor tacrine agrees with our previous studies (8, 10) and supports the idea that OBX-induced impairment of object recognition performance involves central cholinergic dysfunction (8, 18).

Interestingly, BS treatment as well as tacrine could significantly ameliorate OBX-induced deficit of novel object recognition. The ameliorative effect of BS on the working memory deficit was further supported by the data obtained from the modified version of the Y-maze test. Previous studies demonstrated that central cholinergic and glutamatergic systems are involved in short-term spatial working memory performance elucidated by the modified Y-maze test since the muscarinic-receptor antagonist scopolamine and the anti-NMDA-receptor antagonist MK-801 interfere with the performance in a manner reversible by AChE inhibitors (9, 28).

In this study, we found that, consistent with previous reports (8 – 10), OBX mice exhibited significantly impaired spatial working memory performance in the modified Y-maze test, and that the impairment was reversed by tacrine and BS but not by imipramine. These findings suggest that BS treatment can exhibit an antidementia effect like tacrine in OBX mice. Taken together with the data obtained using an object recognition test, it is likely that BS has the potential to improve both
We analyzed the expression levels of synaptic plasticity–related signaling proteins, a molecular biological feature of learning and memory (8, 29, 30), to understand the mechanism underlying the effects of BS on the impaired cognitive performance of OBX animals. Previous studies have reported that glutamatergic systems, such as NMDAR1 and GluR1, are one of the molecular biological bases underlying learning and memory, as well as depression, and that glutamate receptor stimulation–triggered phosphorylation of some key protein such as NMDAR, AMPAR, CaMKII, and CREB is a molecular mechanism underlying neuroplasticity in the hippocampus (31 – 33). Indeed, stimulation of AMPA- and NMDA-type glutamate receptors increases the intracellular Ca²⁺/Na⁺ level via the glutamate-gated cation channels on neuronal membranes, leading to the activation of calmodulin and other Ca²⁺-dependent enzymes, and thereby elicits phosphorylation of subunits of NMDAR and AMPAR at glutamatergic synapses via the activation of protein kinases A and/or C, CaMKII (32). Moreover, autophosphorylation of CaMKII triggered by Ca²⁺-dependent activation of calmodulin plays an important role in the conversion of short-term memory to long-term memory (18). A phosphorylated form of CREB is also known to play a role in the transcription of late downstream genes encoding proteins such as neurotrophic/growth factors which have been implicated in memory formation (33) and depression (34).

In this study, we focused on these factors for the following reasons: First, previous reports from this laboratory and others (9, 18, 27) demonstrated that OBX deteriorates the septo-hippocampal cholinergic system and thereby induces learning and memory performance deficits. Secondly, cholinergic systems affect glutamate receptor function via the activation of muscarinic receptors coupled with Gq/11-PKC signaling systems and thereby modulate glutamatergic neurotransmission (9, 35, 36). As shown in Fig. 5, OBX significantly reduced the levels of p-GluR1, p-NMDAR1, p-CaMKII, and p-CREB in the hippocampus without affecting the basal expression levels of non-phosphorylated forms of these proteins. These findings agree with our previous reports (8) and indicate that cognitive deficits observed in OBX animals are at least partly due to OBX-induced dysfunction of the synaptic plasticity–related neuronal signaling system in the hippocampus. This idea is supported by the fact that OBX-induced dysfunction of the aforementioned neuronal signaling systems was significantly ameliorated in the OBX groups, the cognitive performance of which was improved by BS and tacrine treatment. Moreover, it is of interest to note that imipramine treatment attenuated only OBX-induced down-regulation of CaMKII phosphorylation in the hippocampus. Considering the data that imipramine failed to affect the cognitive dysfunction of OBX animals, it is likely that an increase in CaMKII autophosphorylation may be insufficient to induce neuroplasticity related to cognitive function.

The present study revealed that administration of tacrine and BS attenuated the OBX-induced down-regulated expression level of ChAT in the hippocampus. OBX-induced decrease in the expression level of ChAT and its reversal by tacrine are indeed consistent with our previous reports (8, 10). Daily tacrine administration–induced protection of septal cholinergic neurons has also been observed in an animal model of type 2 diabetes, the cognitive dysfunction of which was ameliorated by tacrine (23, 37, 38), suggesting that elevation of endogenous acetylcholine protects cholinergic neuron from degeneration under pathological conditions. Interestingly, in this study, we found that systemic administration of BS, as well as of tacrine, inhibited the ex vivo activity of AChE in brain tissue. Therefore, a possible explanation for the effect of BS on ChAT expression in OBX animals is that BS may elevate the endogenous acetylcholine level via its tacrine-like action and thereby protect the septo-hippocampal cholinergic systems from OBX-induced neurodegenerative damage in the brain. This mechanism is also very likely to be involved in ameliorating/enhancing the effects of BS on the synaptic plasticity–related neuronal signaling system and cognitive performance in OBX animals, since evidence indicates that endogenous acetylcholine exhibits a facilitatory role in the NMDA-receptor function via M₁ muscarinic receptors in the brain (36) and that the M₁ receptor–mediated cognitive behavior is mediated by neurosignaling pathways including CREB phosphorylation and BDNF expression and secondary messenger cascades, like Gα₁₁-PKC signaling, and intracellular Ca²⁺ mobilization (36).

The present study also investigated using the TST as a model to detect depression-like behavior (39), whether BS treatment affects emotional deficits that are distinctively observed in OBX animals (10, 40). The vehicle-treated OBX mice showed significantly prolonged immobility time in a manner reversible by imipramine treatment in the TST. These data agree with previous studies (10, 21) and indicate that increased immobility of OBX animals in this test can be used as an index of a behavioral symptom relevant to depression. It should be noted that the depression-like behavior deficits caused by OBX were ameliorated in the BS-treated OBX group, as well as in the imipramine-treated OBX animals. These findings raise the possibility that BS has an antidepressant-like effect. This idea seemed to
be supported by our recent observations that BS administration exhibited imipramine-like effects in an animal model of chronic mild stress (Mizuki et al., unpublished data).

The mechanism(s) by which BS exhibits the anti-depressant-like effect is unclear. The present study suggested involvement of synaptic plasticity–related signaling and central cholinergic systems in the ameliorative effects of BS and tacrine on OBX-induced memory deficits. However, considering the failure of tacrine to ameliorate depression-like behavior of the OBX animals, it is very likely that the anti-depressant-like effect of BS is mediated by a mechanism(s) differing from that implicated in BS-induced amelioration of cognitive deficits caused by OBX. Nevertheless, further investigation is required to clarify the exact mechanisms involved in the anti-dementia drug-like and antidepressant-like effects of BS.

It is still unclear which chemical constituents account for the anti-dementia drug-like and anti-depressant-like effects of BS observed in OBX animals. However, a speculative explanation for the effects of BS is that some chemical constituents of BS like isoflavonolignans such as butesuperin A, B, and (−) medicarpin may play an important role in the behavioral and neurochemical effects of BS in OBX animals. Ma et al. (4) found that butesuperin A and B exerted inhibitory activities against phosphodiesterase type 3A and type 5 in vitro, and recent studies demonstrated that selective phosphodiesterase-5 inhibitors such as Sildenafil, which are used for ED therapy, ameliorated emotional deficits like depression (41, 42). Moreover, (−) medicarpin is reportedly an activator of the neurogenin2 promoter (43). Neurogenin2 is involved in neural differentiation and neurogenesis (44). Although no information is currently available on whether these chemicals are able to affect the ex vivo activity of AChE like BS, these constituents are likely to contribute to the amelioration of cognitive dysfunction and depression-related behavior in OBX animals. This possibility needs to be examined by pharmacokinetic analysis of chemical constituents which can cross the blood-brain barrier and be detected in the brain tissue after systemic administration of BS. Nevertheless, further investigations are required to have a better understanding of the mechanism underlying the action of BS.

In summary, the present study has demonstrated that daily administration of BS ameliorates OBX-induced cognitive and emotional disturbance via different neuronal mechanisms and that the effect of BS on the cognitive function in OBX animals is mediated by facilitating the neuro-signaling system in the hippocampus and central cholinergic system.
