Abstract—Cadmium chloride solution (contained 146 PPM of Cd) was administered to mice as drinking fluid for 90 days. Carbonic anhydrase activity was unaffected in blood, liver and kidneys 10 days after administration, however, enzymic activity was significantly reduced in all three organs thereafter. Catalase activity was unchanged until day 31, but was significantly reduced in all organs thereafter. Hemoglobin levels remained unchanged after 10 and 20 days administration, but were significantly reduced thereafter.

Time course of response of carbonic anhydrase and catalase activities and blood hemoglobin level to CdCl₂·2½H₂O in a dose of 10 mg/kg were examined at intervals ranging from 4 to 24 hr after a single s.c. injection. Carbonic anhydrase activity in liver, kidney and blood was significantly decreased every time, however, catalase activity in the above organs as well as the blood hemoglobin level did not change at any time.

Whole-body retention of orally administered ¹¹⁵mCdCl₂ with or without the carrier was examined at one week intervals for 30 days. Whole-body retention of ¹¹⁵mCd was significantly less in the carrier group than in the carrier-free group. Average Cd uptake for 30 days was 0.56 µg/day in the carrier-free group and 0.1 mg/day in the carrier group. Cd concentration in liver and kidneys on day 31 was 0.04 and 0.15 PPM respectively in the carrier-free group and each 24 PPM in the carrier group.

Various metabolic disturbances in humans induced by chronic cadmium (Cd) poisoning are increasing with the increased use of Cd in modern industry. Furthermore, chronic Cd intoxication is termed “Itai-itai disease” in Japan and establishment of diagnostic and therapeutic methods are urgently required.

Although the diagnosis based on the functional and/or morphological examination of blood, liver, kidney, lung and bones are useful to determine Cd poisoning, extensive studies on the early diagnosis of this poisoning as well as systematic and reliable methods have not yet been established. Moreover, biochemical indices which are specific and sensitive to Cd and have a correlation with the concentration of Cd in blood, urine and feces are still unavailable.

The theme of this paper was reported at the 45th Annual Meeting of Japanese Pharmacological Society in April, 1972.
Hypochromic anemia (1) and proteinuria (2) in cadmium poisoning are well established, but changes in the enzyme system in serum are still incomplete. Stowe and Gover (3) reported that serum GOT, GPT, alkaline phosphatase and LDH isozyme values were within normal limits in cadmium-poisoned rabbits. Jacobs et al. (4) reported that Cd acts in vitro as an uncoupler on the oxidative phosphorylation in liver mitochondria.

As for the effect of cadmium on carbonic anhydrase, Meldrum and Roughton (5) previously reported negative results on blood enzymic activity in vitro. Whereas, Hodgen et al. (6) recently reported that CdCl₂ acts in vivo and in vitro as an inhibitor on carbonic anhydrase of rat testes. Johnson and Walker (7) also reported similar results, however, the effect of Cd on carbonic anhydrase activity in organs other than the testis has not been observed. Our in vivo experiments demonstrated that carbonic anhydrase activity was inhibited in blood, liver and kidney after CdCl₂ treatment. Experimental data are outlined below.

MATERIALS AND METHODS

Adult male ddN strain mice weighing approx. 30 g were used. The animals were fed a commercial solid diet (Oriental Co.) and tap water ad lib. until the start of the experiment. Experiments completed, the animals were sacrificed by decapitation, liver and kidneys were removed and homogenized in a Potter-Elvehjem type glass-teflon homogenizer with 0.25 M sucrose adjusted to pH 7.4 with 1 M Tris buffer solution. The tissue homogenates were centrifuged in a refrigerated centrifuge at 0°C for 20 min (9,000 × g) to sediment the nuclei, mitochondria and red blood cells. The supernatant was decanted and used as enzyme sample. In the case of blood, 100-fold and 400-fold diluted blood with distilled water was used for the assay of carbonic anhydrase and catalase activities, respectively. Carbonic anhydrase activity was manometrically assayed by the method of Altschule and Levis (8) and catalase activity was examined by our manometric method (9). Protein content of enzyme sample was determined by Biuret reaction (10) with crystalline bovine serum albumin (Sigma Chem. Co.) used as protein standard. Both enzymic activities were expressed per milligram protein. Hemoglobin concentration in blood was measured by spectrophotometric method (11). In some cases, blood hemoglobin contained in liver and kidney supernatant which was obtained from 105,000 × g centrifugation for 90 min was measured by the same method.

In the tracer experiment, ¹¹⁵CdCl₂ was used. Whole-body radioactivity was determined with a whole-body animal counter and radioactivity in liver and kidney was measured using a G-M counter.

RESULTS

Effect of oral administration of cadmium chloride on the activities of carbonic anhydrase and catalase and hemoglobin level

Tap water containing 146 PPM of Cd was given ad lib. to 5 experimental groups of 5 mice for 10, 20, 30, 60 and 90 days, respectively. Five control groups were given tap
DIAGNOSIS OF CADMIUM POISONING

As shown in Table 1, carbonic anhydrase activities in liver, kidney and blood remained unchanged after 10 days administration, whereas significant decreases were observed in all the three organs thereafter. Catalase activity in liver, kidney and blood was not affected after 10, 20 and 30 days administration, however, the enzymic activity decreased significantly after 60 and 90 days administration (Table 2). The degree of inhibition in catalase activity was less than that in carbonic anhydrase activity. Blood hemoglobin level was unaffected until 20th day with a significant decrease thereafter (Table 2).

Effect of subcutaneous injection of cadmium chloride on the activities of carbonic anhydrase and catalase and hemoglobin level

Fig. 1 shows the changes of carbonic anhydrase activity in liver, kidney and blood at 4, 8, 16 and 24 hr after s.c. injection of CdCl₂·2½H₂O in a dose of 10 mg/kg. Carbonic anhydrase activity gradually decreased after a single injection of Cd and the maximal decrease was observed at 8 hr in the kidney and 16 hr in the liver and blood. Catalase activity and blood hemoglobin concentration in the three organs showed no sig-

significant changes at any time (Figs. 2 and 3).

As carbonic anhydrase activity is highest in blood, it appears necessary to ascertain the contamination of liver and kidney samples by blood as well as the influence on the

carbonic anhydrase activity in the liver and kidney. Therefore, the same experiment was repeated again and enzymic activity was examined 8 hr after Cd injection. As shown in Fig. 4, in both control and experimental groups, an approx. linear relation was observed between enzymic activity and blood hemoglobin within final concentration ranges of approx. 0.1-0.6 μM which correspond to diluted blood from 16,000 to 4,000 fold. Tables 3 and 4 show the true enzymic activity of liver and kidney which was corrected for the contaminated blood enzymic activity. It may be concluded from the above results that true enzymic activity in both liver and kidney is also decreased by Cd administration with contaminated blood having little influence therein.

### Absorption and distribution of ¹¹⁵mCdCl₂

In control group 50 μCi/l of carrier-free ¹¹⁵mCdCl₂ solution (contained 0.35 PPM of Cd) and in experimental group 50 μCi/l of carrier-containing ¹¹⁵mCdCl₂ solution (contained 146 PPM of Cd) were given as drinking fluid ad lib. respectively. Whole-body radioactivity was measured at one week intervals up to day 31. As shown in Fig. 5 and Table 5, whole-body retention of ¹¹⁵mCd was significantly less in the carrier group. The average Cd uptake for 30 days (as computed from specific radioactivity between radioactive and non-radioactive Cd) was 0.56 μg/day in the carrier-free group and 0.1 mg/day in the carrier group. Cd concentrations in liver and kidney at day-31, as computed from ¹¹⁵mCd uptake rates according to specific radioactivity, were 0.04 PPM and 0.15 PPM respectively in the carrier-free group and 24 PPM each in the carrier group (Table 5).

All values indicate mean±S.D. Carbonic anhydrase activity in A and D is expressed per milligram of protein. Enzymic activity in C was calculated from Fig. 4.

*P<0.05 when compared with control values.
As mentioned in the introduction, several investigators have attempted to use the changes of some enzymic activities as diagnostic indices of Cd poisoning however, more sensitive reactions to Cd have yet to be found.

Meldrum and Roughton (5) have reported previously that Cd (CdSO₄ and CdCl₂) had no in vitro effect on the carbonic anhydrase activity of Ca₃(PO₄)₂ purified enzyme preparation obtained from ox corpuscles, although the enzymic activity was inhibited in vitro by ZnSO₄, HgCl₂, CuSO₄, AgNO₃, HAuCl₄ and Va (sulfate). It is strange however that Cd (CdSO₄ and CdCl₂) which belong to the same group as Zn and Hg in the periodic table do not exert any changes on the blood enzymic activity. On the other hand, Hodgen et al. (6) reported a decrease of carbonic anhydrase activity in rat testis in the early stage after a single s.c. injection of CdCl₂ with an increase of its enzymic activity in the later stage. They suggested that the increased enzymic activity may be caused by a haemorrhage in the testis. The experimental results reported by Johnson and Walker (7) with rat and
domestic fowl testis are similar to the above. We also have observed the inhibitory effect of Cd on carbonic anhydrase activity of mouse testes in vivo (unpublished).

In the present experiments, the effect of Cd on both carbonic anhydrase and catalase activities from mouse liver, kidney and blood were examined and it was found that chronic administration of Cd inhibited enzymic activities. We previously observed however that carbonic anhydrase and catalase activities were inhibited in the liver damaged by carbon tetrachloride or ethionine administration without significant changes of blood enzymic activity in many cases (9). Furthermore, decreases of liver carbonic anhydrase activity were also observed in cancer-bearing mice (12, 13) without any significant changes in the enzymic activity of kidney and blood regardless of the presence of hypochromic anemia. These data indicate that the decrease of liver carbonic anhydrase activity is not specific to Cd poisoning and change of blood enzymic activity does not always agree with that in hemoglobin concentration.

In the present experiments, decrease of blood enzymic activity did not accompany the decrease of hemoglobin concentration in acute Cd poisoning (Figs. 1 and 3). Fox et al. (14) reported that anemia is the most severe effect of Cd, however, we assume that this was seen when a large dose of Cd was given over a long time and blood carbonic anhydrase activity was more sensitive to Cd than hemoglobin concentration in an early stage. This reaction appears useful as an index in acute Cd poisoning however, both blood enzymic activity and hemoglobin concentration were decreased by chronic Cd administration, the changes in the latter being greater than in the former.

The precise mechanism of inhibitory action of Cd on carbonic anhydrase activity in liver, kidney and blood is not clear at present, however, the following hypothesis can be made. In acute Cd poisoning, decrease of blood enzymic activity may have no direct relation with hypochromic anemia. Gunn et al. (15) have reported that some thiol compounds, e.g., cysteine and BAL prevented vascular damage to mouse testis caused by Cd, though other thiol compounds, e.g., glutathione and methionine had no protective effect. These data seem to indicate a direct action of Cd on SH radical in carbonic anhydrase molecules as seen in the case of mercury (16). Furthermore, Cd may inhibit enzyme synthesis, although this subject has so far not been given recognition.

It is well known that carbonic anhydrase is a zinc-metalloenzyme. If Zn concentrations or enzymes are diminished by Cd an inhibition of the enzymic activity may be induced as a consequence. Several data are however inconstant with this assumption: Fox et al. (14) have reported that Cd produced an increased concentration of Zn in the erythrocytes but a decreased concentration in the tibia, whereas the Zn concentration in the liver and kidney was not affected. Powell et al. (17) have reported that dietary Cd decreased absorption and tissue distribution of \(^{65}\)Zn in goats. Gunn et al. (18) have reported that Cd in rats interferes with fecal excretion of \(^{65}\)Zn, resulting in an increased retention of radioactive Zn in liver and kidney. These data indicate a complicated relation between Zn and Cd. The interactions between Zn, Fe, Cu and Cd may also play an important part in this phenomena (19, 20). Antagonism between Zn and Cd affecting carbonic
anhydrase activity is not yet clear, however in view of the above observations, it appears necessary to consider in conjugation with Cd concentration in blood, excreta and organs as well as other laboratory data in the diagnosis of chronic Cd poisoning.

Tracer experiments with $^{115m}$Cd disclosed the fate of Cd which could not be determined by other analytical methods. When Cd concentrations in liver and kidneys are taken against the changes in enzymic activity, a considerable low concentration of Cd can affect the enzymic activity. These observations indicate the significance of the enzyme in Cd poisoning.

Liver and kidney tissues obtained from Cd-water drinking animals for 90 days were examined morphologically. No alterations were seen. After a single s.c. injection of Cd, only hyperemia in the testes was observed macroscopically with no pathological findings in liver and kidneys.
