Abstract — The effect of systemically injected $\alpha_1$- and $\alpha_2$-adrenoceptor agonists and antagonists on ACTH secretion was studied in rats. Epinephrine, norepinephrine, phenylephrine, clonidine, B-HT933, and B-HT920 caused a significant and dose-related increase of the ACTH concentration in the serum. The order of median effective dose (ED50) of these drugs on ACTH secretion was as follows: epinephrine = norepinephrine < B-HT920 < clonidine < phenylephrine < B-HT933. Isoproterenol, a $\beta$-adrenoceptor agonist, had no effect on ACTH secretion. ACTH secretion induced by epinephrine or phenylephrine was significantly inhibited by $\alpha_1$-adrenoceptor antagonists, phentolamine and phenoxybenzamine. However, propranolol, a $\beta$-adrenoceptor antagonist, had no effect on ACTH secretion induced by epinephrine. Prazosin, an $\alpha_1$-antagonist, and yohimbine, an $\alpha_2$-antagonist, significantly blocked ACTH secretion induced by phenylephrine, an $\alpha_1$-agonist, and B-HT933, an $\alpha_2$-agonist, respectively. ACTH secretion induced by norepinephrine or a low dose of clonidine was inhibited by both prazosin and yohimbine. However, ACTH secretion induced by a high dose of clonidine was blocked only by prazosin. In rats with complete deafferentation of the medial basal hypothalamus (MBH), ACTH secretion induced by epinephrine, norepinephrine, and clonidine was significantly blocked, as compared with intact rats. These results suggest that both peripheral $\alpha_1$- and $\alpha_2$-adrenoceptors are involved in ACTH secretion induced by systemically injected adrenergic drugs in rats, and intact neural pathways entering the MBH are necessary for this ACTH releasing action.

Epinephrine activates the pituitary-adrenal system and causes release of adrenocorticotropic hormone (ACTH) in animals (1–5) and in man (6). Since this effect is blocked by $\alpha_1$-adrenoceptor antagonists, the epinephrine induced ACTH secretion is considered to be mediated by $\alpha_1$-adrenoceptors (7–9). However, some investigators have shown the involvement of a $\beta$-adrenoceptor mechanism in the control of the pituitary-adrenal system (10, 11). Recently, $\alpha$-adrenoceptors have been subclassified into $\alpha_1$- and $\alpha_2$-types according to the relative potencies and affinities of agonists and antagonists (12, 13). The first aim of this study is to confirm that $\alpha$-adrenoceptors are involved in ACTH secretion and furthermore, to investigate which of the two $\alpha$-adrenoceptors ($\alpha_1$ and $\alpha_2$) is mainly responsible for ACTH secretion in rats. Prazosin and yohimbine were used as selective $\alpha_1$- and $\alpha_2$-adrenoceptor antagonists, respectively, and the azepine derivatives B-HT933 (azepexole) and B-HT920, which are new experimental antihypertensive compounds, were used as highly selective $\alpha_2$-adrenoceptor agonists (14–18).

The medial basal hypothalamus (MBH) is well known to be essential for regulation of ACTH secretion. Some stressful stimuli stimulate ACTH release by neural pathways entering the MBH, while others stimulate it even after the deafferentation of the MBH (19–23). The second aim of this study is to investigate whether or not the intact neural pathways into the MBH is necessary for ACTH secretion induced by systemic in-
jection of adrenergic stimulating drugs. For this purpose, complete hypothalamic deafferentation around the MBH was performed using a Halász-type knife in rats.

Materials and Methods

Animals: Adult male rats of the Donryu strain weighing about 200 g were kept in an air-conditioned room (temperature 24±1°C, 55±5% humidity) with a controlled light-dark cycle (lights on at 6:30 a.m. and lights off at 6:30 p.m.). Food (CE-2 cubic diet, Nihon Clea Co., Tokyo) and water were given ad libitum.

Hypothalamic deafferentation: Hypothalamic deafferentation was performed according to the method of Halász and Pupp (24), with minor modifications. Deafferentation was made in a stereotaxic instrument under pentobarbital anesthesia (35 mg/kg i.p.) using a Halász-type knife with a 2.0 mm height and 1.7 mm radius. Complete cuts were made around the MBH: rostrally the knife was turned near the posterior edge of the optic chiasm, caudally in front of the mammillary body (Fig. 1). In the sham-operated rats, the knife was lowered into the brain to a ventral surface of the hypothalamus, without moving or turning it any further. The rats operated on were housed in individual cages. Experiments were done 5 to 6 days after the operation. Completeness of the hypothalamic cuts was ascertained histologically in each case. The brains were fixed in 10% formaldehyde, embedded in paraffin, cut into serial sections (10 μm thickness) and stained with hematoxylineosin.

Drugs: The following drugs were used: (1) agonists: epinephrine HCl (Bosmin, Daiichi), dl-norepinephrine HCl (Noradrenalin, Sankyo), phenylephrine HCl (Neo-Synesin, Kowa), I-isoproterenol HCl (Proteron-I, Nitsukien Chemical), clonidine HCl (Tokyo Kasei), B-HT933 (Azepeole, 2-amino-6-ethyl-5,6,7,8-tetrahydro-4H-oxazolo-(4,5-d)-azepine, 2HCl) (Nippon Boehringer Ingelheim, Thomae), B-HT920 (2-amino-6-allyl-5,6,7,8-tetrahydro-4H-thiazolo-(4,5-d)-azepine, 2HCl) (Nippon Boehringer Ingelheim, Thomae) and (2) antagonists: phentolamine mesylate (Regitine Ciba), phenoxybenzamine HCl (Dibenzyline, Tokyo Kasei), propranolol HCl (Inderal, Sumitomo Chemical), prazosin HCl (Pfizer Taito), yohimbine HCl (Nakarai Chemical). Drug solutions for injection were freshly prepared before each experiment. They were diluted with saline, except for phenoxybenzamine, prazosin, and yohimbine. Phenoxybenzamine was dissolved in propylene glycol-saline (4:3, v/v) solution and diluted with the same vehicle. Prazosin was emulsified in 1% tween 80, 49% paraffin liquid and 50% saline, and diluted with the same emulsified vehicle. Yohimbine was dissolved in distilled water and diluted with saline.

General procedures: Drugs were injected intraperitoneally (i.p.), except for prazosin which was injected subcutaneously (s.c.). The injection volume was 0.2 ml per 100 g body weight. Control animals were injected

with an equal volume of saline or the vehicle. Rats were pretreated with antagonists and were killed by decapitation 10 min after the injection of agonists. The decapitation time was arranged from 9:00 to 11:00 a.m. in all the experiments. The trunk blood was collected into a plastic tube and rapidly cooled in ice-water. The serum was separated by centrifugation at 4°C. ACTH in the serum was adsorbed to QUSO G32 (Philadelphia Quartz Co.). QUSO powder was washed with deionized-distilled water, and ACTH was extracted with 40% acetone in 1% acetic acid. The extract was evaporated to dryness in a vacuum centrifuge at 45°C. As a standard for determining ACTH in the serum, synthetic ACTH1-24 (Cortrosyn, N.V. Organon) was added into ACTH-free rat serum. The standard ACTH1-24 was treated by the same method that was used for the samples as described above. The details of these methods can be seen in a previous paper (25). The dried sample and the dried standard ACTH1-24 were stored at -20°C until the ACTH bioassay.

Preparation of isolated rat adrenal cell suspension: Isolated rat adrenal cell suspension was prepared by the method of Sayers et al. (26) with the following modification: Decapsulated rat adrenal glands were cut into small pieces and put into trypsin solution which contained 0.25% trypsin (1:250, Difco Laboratories) and 0.3% bovine serum albumin (BSA) (Fraction V from bovine plasma, Armour Pharmaceutical Co.) in Ca2+-free Krebs-Ringer-bicarbonate buffer containing 0.2% glucose (KRB-G). KRB-G was freshly prepared and saturated with a gas mixture of 5% CO2-95% O2. Trypsin digestion was carried out with gentle stirring at 35°C for 10 min for each step. The first fluid which contained the broken cells was discarded. A fresh trypsin solution was added to the residual adrenal tissues, and the trypsin digestion was continued for 10 min. The fluid containing the isolated cells was filtered through an 80-mesh platinum sieve and pooled in an ice-cold flask. This procedure was repeated several times until the tissues were digested by trypsin completely. The pooled fluid was centrifuged at 700 r.p.m. for 10 min at 4°C. After centrifugation, the precipitated cells were suspended in 5 ml of KRB-G (2.54 mM Ca2+) containing 0.2% soybean trypsin inhibitor (Type 1-S, Sigma Chemical Co.) and 0.5% BSA. The cell suspension was centrifuged again at room temperature. The precipitated cells were resuspended in an appropriate volume of KRB-G (5.08 mM Ca2+) containing 0.1% soybean trypsin inhibitor and 0.5% BSA and filtered again. The resuspended cells were preincubated at 35°C for 30 min. The preincubated cell suspension was used for the experiment. All procedures were carried out in plastic tubes and siliconized glass ware and pipettes.

ACTH bioassay: The dried sample and standard ACTH1-24 were incubated with the isolated adrenal cell suspension by shaking at 37.5°C for 90 min under a gas phase of 5% CO2-95% O2. The amount of produced corticosterone was measured fluorometrically by the method of Silber et al. (27) with the modification that n-hexane and sulfuric acid-ethanol (7:3, v/v) were used instead of isooctane and 30N sulfuric acid, respectively. The amount of ACTH in the sample was calculated from the dose-response curve obtained with the standard ACTH1-24. Statistical analysis was performed by Student's t-test.

Results
The ACTH concentration in the serum of untreated rats (n=23) was 10.0±0.7 pg/ml (mean±S.E.), and that at 10 min after the saline injection was 10.2±0.4 pg/ml. Figure 2 shows the log dose-response relationships between doses of various adrenoceptor agonists and antagonists and the concentrations of ACTH in the rat serum. Ten minutes after the injection of various α-adrenoceptor agonists, the ACTH concentration in the serum was increased dose-dependently. However, isoproterenol, a β-adrenoceptor agonist, had no effect on ACTH secretion at a dose of 0.05 to 0.4 mg/kg. Large doses of α-adrenoceptor antagonists, phentolamine, phenoxybenzamine, and yohimbine, greatly stimulated ACTH secretion by themselves. The log dose-response curves were used for calculating median effective dose (ED50) of various α-adrenoceptor agonists on ACTH.
secretion. The order of ED50 was as follows: epinephrine = norepinephrine < B-HT920 < clonidine < phenylephrine < B-HT933. Epinephrine and norepinephrine were about equally potent. B-HT933 was less effective than the other drugs (Table 1).

Figure 3 shows the time courses of the ACTH concentration in the serum after a single injection of phenylephrine (A) and clonidine (B). When 1.5 mg/kg of phenylephrine was injected, the ACTH concentration in the serum increased rapidly and reached its maximum level at 10 min. Then it decreased, approaching the normal level at 60 min. A similar time course was also observed with a single injection of 0.1 mg/kg of epinephrine (data not shown). The injection of 1.5 mg/kg of clonidine also produced a rapid increase in the serum ACTH level and a subsequent prolonged secretion of ACTH until 30 min. The ACTH concentration then decreased gradually, but it was

still at a relatively high level 60 min after the
injection. Since the maximum concentration
of ACTH was found at 10 min in these cases,
rats were decapitated 10 min after the
injection of adrenoceptor agonists throughout
the experiments.

Figure 4 shows the effect of pretreatment
with \(\alpha\)-adrenoceptor antagonists, phentol-
amine and phenoxybenzamine, on ACTH secretion induced by epinephrine or phenylephrine. ACTH secretion induced by epinephrine was significantly inhibited by phentolamine (2.5 mg/kg). Phenylephrine-induced ACTH secretion was also significantly blocked both by phentolamine (2.5 mg/kg) and by phenoxybenzamine (1 or 2 mg/kg). However, propranolol (0.5 to 2 mg/kg), a β-adrenoceptor antagonist, did not inhibit ACTH secretion induced by 0.1 mg/kg of epinephrine (data not shown). In Fig. 4, the dose of each agonist was so chosen that it produces about 100 pg/ml of ACTH secretion. However, we could not obtain constantly 100 pg/ml of ACTH secretion for each agonist because individual rats had a different sensitivity to the drug. Then we repeated the experiment several times with the same dose for each agonist. In order to summarize the results, the effect of agonist after the injection of antagonist was shown as a percentage of the control. In later experiments, the results were also shown as a percentage of the control.

Figures 5 and 6 show the effect of pretreatment with prazosin, an α₁-antagonist, or yohimbine, an α₂-antagonist, on ACTH secretion induced by phenylephrine, norepinephrine, B-HT933, or clonidine. Prazosin (0.5 to 2 mg/kg) significantly antagonized ACTH secretion induced by phenylephrine, but yohimbine (0.5 or 1 mg/kg) had no statistically significant effect on the ACTH secretion induced by it. Norepinephrine-induced ACTH secretion was markedly blocked both by prazosin (1 or 2 mg/kg) and yohimbine (0.5 mg/kg). B-HT933-induced ACTH secretion was significantly inhibited by yohimbine (0.25 to 2 mg/kg), but it was not inhibited by prazosin (0.5 to 2 mg/kg). A similar result was also obtained with 20 mg/kg of B-HT933. ACTH secretion induced by 0.5 mg/kg of clonidine was significantly blocked both by prazosin (2 mg/kg) and by yohimbine (0.5 to 2 mg/kg), but that induced by 1 mg/kg of clonidine was inhibited only by prazosin. When 0.25 mg/kg of clonidine was injected, yohimbine was more effective than prazosin.

### Figures 5 and 6

**Fig. 5.** Effect of pretreatment with prazosin or yohimbine on ACTH secretion (% of control) induced by phenylephrine, norepinephrine, or B-HT933. Pretreatment time of prazosin and yohimbine was 30 min and 10 min, respectively. Control responses were obtained from pretreatment with vehicle or saline. Rats were decapitated 10 min after the injection of phenylephrine, norepinephrine, or B-HT933. The numbers above the bars are the number of rats, and vertical bars represent the mean±S.E. *P<0.05, **P<0.01, ***P<0.001: Significantly different from each control value.
Fig. 6. Effect of pretreatment with prazosin or yohimbine on ACTH secretion (% of control) induced by clonidine. Pretreatment time of prazosin and yohimbine was 30 min and 10 min, respectively. Control responses were obtained from pretreatment with vehicle or saline. Rats were decapitated 10 min after the injection of clonidine. The numbers above the bars are the number of rats, and vertical bars represent the mean±S.E. *P<0.05, **P<0.01, ***P<0.001: Significantly different from each control value.

Fig. 7. Effect of complete hypothalamic deafferentation on ACTH secretion (% of intact) induced by epinephrine, norepinephrine or clonidine. The drug was injected 5 to 6 days after hypothalamic deafferentation. Rats were decapitated 10 min after the injection of the drug. The numbers above the bars are the number of rats and vertical bars represent the mean±S.E. ***P<0.001: Significantly different from each intact value.

The effect of complete hypothalamic deafferentation on ACTH secretion is shown in Fig. 7. Epinephrine and norepinephrine produced ACTH secretion in sham-operated rats similar to that in intact rats. In deafferented rats, injection of epinephrine (0.3 mg/kg), norepinephrine (0.2 mg/kg), and clonidine (1 mg/kg) did not increase the
ACTH concentration in the serum: ACTH secretion induced by these drugs was markedly inhibited by hypothalamic deafferentation. In deafferentated rats, the ACTH concentration in the serum at 10 min after the saline injection was 10.0±4.1 pg/ml, and that at 10 min after the epinephrine injection was 22.3±8.2 pg/ml. A significant difference between these results could not be observed, but the ACTH concentration in the serum after epinephrine injection was always higher than that after saline injection.

**Discussion**

In this paper it was confirmed that when various adrenergic drugs are systemically injected, α-adrenoceptors are mainly responsible for ACTH secretion and β-adrenoceptors are not important for it. However, there are some reports that ACTH secretion is mediated by β-adrenoceptors (10, 11). Their experimental conditions are different from our conditions. Tilders et al. (10) infused drugs into a lateral tail vein of female Wistar rats under anesthesia. The influence of anesthesia on ACTH secretion and the difference in strain can not be disregarded. Fahringer et al. (11) used a higher dose of phentolamine. As will be discussed later, higher doses of α-adrenoceptor antagonists produced ACTH secretion by themselves. As previously mentioned, α-adrenoceptors have been subclassified pharmacologically into α₁- and α₂-adrenoceptors (12, 13). α₁-Adrenoceptor was preferentially stimulated by phenylephrine and metoxamine, and it was inhibited by prazosin. α₂-Adrenoceptor was preferentially stimulated by guanabenz and clonidine, and it was blocked by yohimbine and clonidine. In the present experiments, ACTH secretion induced by phenylephrine was completely blocked by prazosin (Fig. 5), and yohimbine inhibited significantly ACTH secretion induced by a low dose of clonidine (Fig. 6) and B-HT933 (Fig. 5). These results suggest that both α₁- and α₂-adrenoceptors are involved in ACTH secretion induced by adrenergic drugs in rats.

Clonidine is generally accepted as an α₂-adrenoceptor agonist. In the present experiment (Fig. 6), ACTH secretion induced by a low dose of clonidine was effectively blocked by yohimbine, while that induced by a high dose of clonidine was blocked only by prazosin. In pithed rats, Timmermans et al. (14) reported similar results that vasopressor responses induced by a low dose of clonidine are blocked only by yohimbine, but those induced by a relatively high dose of clonidine are markedly inhibited by prazosin. Therefore, it is reasonable to assume that clonidine has a higher affinity for the α₂-adrenoceptor than for the α₁-adrenoceptor. Low doses of clonidine stimulate mainly α₂-adrenoceptor, while high doses of clonidine stimulate α₁-adrenoceptor in addition to α₂-adrenoceptor.

Some of the α-adrenoceptor antagonists, phentolamine, phenoxybenzamine and yohimbine, caused a great stimulation of ACTH secretion by themselves at higher doses (Fig. 2). A similar result has been observed by Ohler and Sevy (7) that dibenamine, an α-adrenoceptor antagonist, itself produces an acute reduction in adrenal ascorbic acid. These results suggest that higher doses of α-adrenoceptor antagonist themselves may have the property of an α-adrenoceptor agonist, or they may involve factors other than an α-adrenergic blockade. High doses of various α-adrenoceptor blocking drugs have been reported to produce pressor responses in dogs (28) and cats (29, 30), which are the remarkable effects of various α-adrenergic agonists.

It is well known that ACTH secretion is increased by various stresses. Fortier has divided ACTH-releasing stressful stimuli into two functionally distinct classes: neural and systemic stimuli (19). Neural stimuli may provide signals for the secretion of corticotropin-releasing factor (CRF) through afferent pathways to the hypothalamic median eminence. Neural afferent pathways are not essential for systemic stimuli. In systemic stimuli, ACTH-releasing neurohormon distinct from CRF, passes by the systemic blood stream directly to the pituitary gland, effecting ACTH release. Therefore, some explanations may be given for ACTH secretion induced by the systemic injection of various adrenergic drugs. The first possibility is the neural passway mediated by the nervous system. Various systemically injected
adrenergic drugs act directly on sympathetic effector cells following interaction with peripheral α-adrenoceptors. These drugs exert an influence upon biochemical reactions and functional responses in all tissues. These responses induced by stimulation of α-adrenoceptors may become the stressor for neural stimuli which produces ACTH secretion. One of the most striking effects of many adrenergic stimulating drugs is that they increase arterial blood pressure due to stimulation of α-adrenoceptors in the vascular system. It seems likely that pressor responses produce strong stresses and yield ACTH release. Up to now, it has not been reported that pressor responses produce ACTH secretion, while there are some reports (7, 31) that ACTH secretion induced by epinephrine is not mediated through the pressor effect. However, the possible role of cardiovascular effects on ACTH secretion cannot be excluded. In the present experiment, trunk blood volume was decreased dose-dependently after clonidine injection. This decrease of the blood volume seems to be due to vasodilation. Clonidine produces some direct peripheral vasodilation (32). Prazosin and yohimbine inhibited both the decrease of the blood volume and the increase of ACTH secretion induced by clonidine. An inverse correlation was found between the blood volume and ACTH secretion (data not shown). In the previous experiment (33), after histamine injection, trunk blood volume was markedly decreased, and this decrease in the blood volume was inhibited by antihistaminic drugs. ACTH concentration in the serum was also increased after histamine injection and this increase was inhibited by antihistaminic drugs. It is generally known that hypotension which arises from hemorrhage causes activation of the pituitary-adrenal system in animals (34–37). Furthermore Gann et al. (38, 39) and Wood et al. (40, 41) have reported that adrenal cortical response to hypotension may be mediated in part by vagal pathways and by carotid baroreceptors. Therefore, these results suggest that the decrease of the circulating blood volume is closely related to the stimulation of ACTH secretion. Changes in blood pressure or blood flow in the periphery which are induced by various adrenergic stimulating drugs may become the stressors and may act as the trigger signals for ACTH secretion. The second possibility is the systemic passway. Epinephrine and norepinephrine cannot easily pass the blood-brain barrier. However, the direct action of these drugs on the median eminence and pituitary gland should not be disregarded because these areas are located outside the barrier. It was shown by Weil Malherbe et al. (42) that 2 min after a rapid intravenous injection, the pituitary gland contained radioactive norepinephrine in high concentration, exceeding that in plasma. Direct action of epinephrine and norepinephrine in anterior pituitary cells in primary culture was also reported by Giguère et al. (43, 44). In the present experiment, ACTH secretion induced by epinephrine was markedly inhibited by complete cuts around the MBH. In deafferentated rats, however, the ACTH concentration in the serum after epinephrine injection tended to be at a higher concentration than that after saline injection, although it was not significantly higher. This may be due to the contribution from the direct action on the pituitary gland or median eminence.

From these results, it is concluded that ACTH secretion induced by systemically injected adrenergic drugs in rats is mediated via both α₁- and α₂-adrenoceptors, and intact neural pathways entering the MBH are necessary for the ACTH releasing action. However, the direct action on pituitary gland or median eminence can not be excluded. It may be partly involved in ACTH secretion induced by these drugs.
