Portomicron remnant and very low density lipoprotein (VLDL) remnant in chickens were prepared by the method using ultracentrifugation (d < 1.019) following an in vitro incubation of portomicron or VLDL prepared from chicken plasma with chicken lipoprotein lipase (LPL) for 2 h at 37°C. The portomicron remnants and VLDL remnants yielded the almost single peak in the elution pattern on Bio-Gel A50m column (1.6 × 50 cm) and the particle sizes were smaller than portomicron and VLDL since the elution of remnants by Bio-Gel A50m was similar to LDL rather than portomicron and VLDL. Chicken remnants had low triacylglycerol contents with high cholesterol and lower apolipoprotein C contents compared to portomicron or VLDL. These findings present the possible procedure to prepare in vitro chicken LPL-generated portomicron- and VLDL-remnants and suggested that the chicken remnants are characterized by a peculiar apolipoprotein composition while resemble to mammalian remnants in the lipid composition and particle size.

**Abbreviations:** VLDL, very low density lipoprotein; LDL, low density lipoprotein; Apo, apolipoprotein; LPL, lipoprotein lipase

**Key words:** broiler chicken, lipoprotein, lipoprotein lipase, portomicron remnant, VLDL remnant

**Introduction**

The obligatory step in the transport of triacylglycerol fatty acids from circulating chylomicron and very low density lipoprotein (VLDL) into tissues is hydrolysis of triacylglycerol core in the lipoprotein particles by lipoprotein lipase (LPL, EC 3.1.1.3) (Nilsson-Ehle et al., 1980). In mammals, plasma chylomicron and VLDL are converted to their remnants, respectively, following LPL hydrolysis with taking off the certain apolipoproteins (Havel et al., 1980). The chylomicron remnants are cleared rapidly from plasma and taken up mainly by low density lipoprotein (LDL) receptor-related protein (LRP) and LDL receptor (Martins et al., 2000), and the clearance is mediated by apolipoprotein (Apo) E and Apo B, respectively. In contrast, VLDL remnants are mainly converted to LDL and taken up by liver through the LDL receptor (Ginsberg, 1998). These findings have been reported practically in experiments on liver membrane binding of lipoproteins generated by milk LPL (Hui et al., 1984), post-heparin plasma (Windler et al., 1988) or remnant- like lipid emulsion (Martins et al., 2000) in mammals.

In chickens, VLDL/vitellogenin receptor (LR8) (95 and 105 kDa) and LRP1 (515 kDa) in the ovary (Schneider et al., 2007) and LDL receptor in liver (Hummel et al., 2003) were identified. There is, however, less information on the lipoprotein metabolism following hydrolysis of portomicron (chylomicron is referred to as portomicron in avians) and VLDL by LPL. In addition, chicken portomicron remnant and VLDL remnant were not characterized until now. Griffin et al. (1992) reported that only 6–7% of portomicron and VLDL triacylglycerols were taken up by the abdominal adipose tissues in broiler chickens. We demonstrated that chicken LPL plays a crucial role for fat accumulation in adipose tissues and the inhibition of LPL catalyzed hydrolysis of triacylglycerol-rich lipoproteins reduces the fat accumulation in chickens (Sato et al., 1999), and also characterized that the chicken-LPL had high Vmax with low Km as compared to rat-LPL (Sato et al., 1997). These findings suggested that the most of VLDL and portomicron hydrolyzed by LPL were converted to remnants to be taken up to the liver by the lipoprotein receptor-mediated endocytosis in chickens, then were resynthesized to newly triacylglycerol rich lipoprotein. In addition, Rajavashisth et al. (1987) observed that the chicken lipoprotein lacked apolipoprotein (apo) E which was found in mammals. In mammals, apo E plays an important role in the metabolism of triacylglycerol-rich lipoproteins, such as VLDL, chylomicrons, and chylomicron
remnants, which mediate the high-affinity binding of apo E-containing lipoproteins to the LDL receptor and members of its gene family, including LRP, VLDL receptor, and the apo E2 receptor (apo E2R) (Cooper, 1997). These data may imply that there is a species difference between chickens and rats in lipoprotein metabolism following LPL catalyzed hydrolysis, especially in the viewpoint of apo E mediated endocytosis in mammals. From a viewpoint to investigate the lipoprotein receptor-mediated endocytosis in chicken lipoprotein remnants, it seems essential to provide the chemical characterization of chicken lipoprotein remnants, which may be generated through chicken adipose tissue LPL-catalyzed hydrolysis.

In the present work with broiler chickens, in order to characterize the lipoprotein metabolism following LPL catalyzed hydrolysis, we show the preparation and characterization of chicken portomicron remnant and VLDL remnant in vitro.

Materials and Methods

Animals
Male broiler chickens (Ross strain, Matsumoto Hatchery, Zao or Ibaragi, Japan) with body weight ranging from 1,500 to 2,000 g were provided. Chickens were fed ad libitum on a commercial grower’s diet for broiler chickens. The blood was collected from the wing vein with EDTA determined by the method of Lowry (1951) or Coomassie protein assay reagent (Pierce) using bovine serum albumin as the standard.

Preparation of Chicken LPL
Acetone powders were prepared from adipose tissues of chickens according to the method of Sato et al. (1997). The crude LPL were prepared by an extraction of the acetone powders with 5 mM sodium barbital buffer (pH 7.5) containing 0.5 M NaCl. All procedures were approved by the “Animal Care and Use Committee” of the Graduate School of Agricultural Science of Tohoku University or Tokyo University of Agriculture and Technology.

Preparation of Chicken LPL
Acetone powders were prepared from adipose tissues of chickens according to the method of Sato et al. (1997). The crude LPL were prepared by an extraction of the acetone powders with 5 mM sodium barbital buffer (pH 7.5) containing 0.5 M NaCl.

Preparation of Portomicron Remnant and VLDL Remnant
Plasma lipoproteins, portomicron (d < 0.96), VLDL (d 0.96-1.016) and LDL (d 1.019-1.063), were prepared by the method of Lindgren (1975) and Hermier et al. (1985) using ultracentrifugation performed HITACHI himac CP 56GII ultracentrifuges (Hitachi Koki, Tokyo, Japan) with a RP65T rotor.

Remnants of lipoproteins, portomicron and VLDL, were prepared by the method of Hui et al. (1984) with slight modifications. Portomicron and VLDL (containing 12 mg triacylglycerols) were incubated for 2 h at 37°C in a solution containing 10 ml of crude chicken LPL (4 mg protein) and 10 ml of 100 mM Tris-HCl buffer (pH 8.6) containing 4% fatty acid-free albumin. This incubation condition was determined by our previous report (Sato et al., 1995). At the end of incubation, the solution was adjusted to a density of 1.063 with solid KBr, overlayered with 2 ml of saline/EDTA with KBr (d = 1.019), and remnants were refloated in a RP65T rotor by centrifugation for 16 hr at 45,000 rpm. The isolated remnants were exchanged for 50 mM Tris-HCl buffer (pH 8.6) by PD-10 column (GE healthcare, Uppsala, Sweden).

Characterization of Remnants
To determine the remnant particle size and polity, lipoproteins were applied to a Bio-Gel A-50m (Bio-Rad Laboratories, CA, USA) column (1.6 × 50 cm), eluted with 0.15 M NaCl containing 1 mM EDTA.

The different classes of lipids in lipoproteins were quantified according to colorimetric methods of triacylglycerol, phospholipid and total cholesterol followed by Fletcher (1968), Takayama et al. (1977) and Richmond (1974), respectively.

Electrophoretic evaluation of portomicron remnant and VLDL remnant apolipoproteins were made using SDS-PAGE (10% gel) by the method of Bouziane et al. (1994) after partial delipidation. Electrophoresis was performed in a Mini-PROTEAN II electrophoresis cell (Bio-Rad Laboratories, CA, USA) at 4°C, for 1.5 hr with 25 mA/gel slab. The gels were then stained with Coomassie brilliant blue G 250.

Other Assays
The protein contents of enzyme and lipoproteins were determined by the method of Lowry et al. (1951) or Coomassie protein assay reagent (Pierce) using bovine serum albumin as the standard.

Statistics
A computer generated SAS applications package was used for statistical calculations (Statistical Analysis System Version 6.03, SAS Institute Inc., Cary, NC). Group data for multiple comparisons were analyzed by ANOVA using a general linear models procedure followed by Duncan’s multiple rang test to test for differences among lipoproteins. The level of significance used in all studies was p < 0.05.

Results
Isolation of Chicken Portomicron Remnant and VLDL Remnant
The chicken portomicron remnants and VLDL remnants isolated by the centrifugation were applied to Bio-Gel A-50m. The portomicron remnants and VLDL remnants were eluted as the almost single peak at 80-110 ml of elution volume and these peaks were almost comparable to a peak obtained by the elution of chicken LDL (Fig. 1). Characteristics of Remnants
Portomicron- and VLDL-remnants were characterized in lipid composition by significantly lower triacylglycerol but higher cholesterol contents than the corresponding native counterparts (Table 1). LDL contained low triacylglycerols with high phospholipids and total cholesterol as compared to portomicron- and VLDL-remnants.

Four major apolipoprotein bands, apo B100, apo A-I, apo C and apo A-IV, were detected on SDS-PAGE analysis of lipoproteins (Fig. 2). The lipoprotein remnants
Values with different superscripts in columns are significantly different (\(\ast\)).

TG=triacylglycerol. PL=phospholipid. TC=Total cholesterol.

were characterized by significantly lower apo C contents than the corresponding native counterparts with the comparable proportion of apo B100. The apo A-I and A-IV contents tended to be higher in the remnants than in portomicron and VLDL (Fig. 2).

**Discussion**

The present data showed that chicken lipoprotein remnants (portomicron remnants and VLDL remnants) could be prepared by *in vitro* partial hydrolysis of chicken lipoproteins by LPL prepared from chicken adipose tissue. The lipoprotein remnants have been largely prepared and characterized through *in vitro* incubation of serum lipoproteins with milk-LPL or post-heparin plasma in mammals (Havel *et al.*, 1980). It is, however, preferable to provide LPL prepared from adipose tissue of respective species instead of milk-LPL or post-heparin plasma on a viewpoint to characterize the remnants in detail. The chicken LPL-generated remnants were eluted as the almost single peak by Bio-Gel A50m gel chromatography. Hui *et al.* (1984) reported that dog chylomicron remnants were prepared by the overnight incubation of chylomicrons with purified milk LPL in which 92% of the triacylglycerols in the dog chylomicrons were hydrolysed. In the preparation of chicken lipoprotein remnants based on the proce-
due of Hui et al. (1984) with the overnight incubation, gel chromatography analysis revealed the similar broad peaks together with portomicron- and VLDL-remnants (data not shown). Our previous study described that the in vitro hydrolysis of plasma portomicron and VLDL by chicken LPL increased linearly with the incubation time to attain the plateau at 50 min (Sato et al., 1995). In addition, we showed that chicken-LPL purified from adipose tissue had high Vmax with low apparent Km as compared to rat-LPL (Sato et al., 1997). It is, therefore, likely that incubation for 2 h with chicken LPL employed in the present study is relevant for the in vitro preparation of chicken remnants and thereby generated the remnants with single peak by Bio-Gel A50m conducted successively.

Chylomicron remnants and VLDL remnants in mammals are characterized by the decreases in triacylglycerol contents, Apo C proteins and particle sizes as compared to chylomicron and VLDL, respectively, while the increases in cholesteryl esters and phospholipids (Havel et al., 1980). In the present study, chicken portomicron- and VLDL- remnants were characterized in the lipid composition by significantly lower triacylglycerol with the corresponding native counterparts while by significantly higher triacylglycerol with the lower cholesteryl contents than LDL. These results showed that the lipid compositions of chicken remnants were similar to those of mammals. The elution pattern of chicken lipoprotein remnants was similar to that of LDL in the present study despite there are marked differences in the lipid composition between remnants and LDL. Chicken remnants prepared in vitro in the present experiment demonstrated the delayed elution as compared to portomicron and VLDL. These results, therefore, indicate that the diameter of chicken remnants were smaller than that of portomicron and VLDL but equal to that of LDL. Mjos et al. (1975) reported that the diameter of remnants was smaller than that of chylomicrons and VLDLs in rats.

The present study showed that LPL-generated remnants had almost comparable apo B100 contents while lower apo C contents as compared to portomicron and VLDL. These findings might indicate that the partial hydrolysis of lipoproteins by LPL released apo C but not apo A-I and apo A-IV (Fig. 2). Windler et al. (1988) reported that the in the preparation of rat chylomicron remnants, the apo B48 and apo E contents were not changed whereas apo A-I, apo A-IV and apo C contents were decreased by LPL-catalyzed hydrolysis. These results suggested that there were species differences in content and function of apo A-I and A-IV in the apolipoproteins between chickens and mammals. In mammals, the clearance of chylomicron remnants is mediated by apo E (Borensztain et al., 1982). Rajavashisth et al. (1987) observed, however, that the chicken lipoprotein lacked Apo E which was found in mammals. It has been reported that apoB is a ligand of chicken lipoprotein receptors (Schneider, 2007). It is, therefore, suggested that chicken apoB100 might be functional as the ligand of the lipoprotein remnant receptors.

Our study showed that the preparation and characterization of chicken portomicron remnant and VLDL remnant in vitro to characterize lipoprotein metabolism following LPL catalyzed hydrolysis in chickens. As the chicken portomicron remnants and VLDL remnants appeared similar characteristics to mammalian remnants except the major apolipoprotein content, it is likely that the chicken remnants are incorporated, in part, by receptor mediated pathway as in mammals. Further investigation on chicken lipoprotein receptor using remnants prepared by the present study may provide possible clues to understand the lipoprotein metabolism following LPL catalyzed hydrolysis in chickens.
