Abstract. [Purpose] The purpose of this meta-analysis was to assess the effects of extracorporeal shock wave therapy (ESWT) on reducing spasticity immediately and 4 weeks after application of ESWT. [Subjects and Methods] We searched PubMed, TCM, Embase, and Scopus from their inception dates through June 2013. The key words “muscle hypertonia OR spasticity” were used for spasticity, and the key words “shock wave OR ESWT” were used for ESWT. Five studies were ultimately included in the meta-analysis. [Results] The Modified Ashworth Scale (MAS) grade was significantly improved immediately after ESWT compared with the baseline values (standardized mean difference [SMD], -0.792 ; 95% confidence interval [CI], -1.001 to -0.583). The MAS grade at four weeks after ESWT was also significantly improved compared with the baseline values (SMD, -0.735 ; 95% CI, -0.951 to -0.519). [Conclusion] ESWT has a significant effect on improving spasticity. Further standardization of treatment protocols including treatment intervals and intensities needs to be established and long-term follow up studies are needed.

Key words: Spasticity, Extracorporeal shock wave therapy, Meta-analysis

(This article was submitted Feb. 27, 2014, and was accepted Apr. 10, 2014)

INTRODUCTION

After injury to the upper motor neurons (UMN) such as the brain or spinal cord, certain clinical deficits present immediately or at delayed times. Weakness and loss of dexterity appear at an early stage followed by various degrees of muscle overactivities. Spasticity or spastic hypertonia elicited by passive stretch of a muscle at rest can interfere with active or passive movement¹⁾. Hyperexcitability of spinal reflexes causes spasticity and spastic hypertonia, but it is not the only mechanism that contributes to spasticity after brain injury. Recent studies indicate that abnormal stretch reflex activity is insufficient to explain increased muscle tone^{2–4)}. Increased stiffness of a muscle during stretching due to changes in collagen tissue and tendons, enhancement of the intrinsic stiffness of muscle fibers, and loss of sarcomeres can lead to subclinical contractures⁵⁾.

Each of the therapeutic interventions to reduce spasticity including physical therapy, occupational therapy, orthoses,

pharmacological treatment, chemodenervation, orthopedic surgery, and neurosurgery has different indications and advantages⁶⁾. There is currently a lack of specific guidelines for the stratification and individualization of therapeutic interventions.

Extracorporeal shock wave therapy (ESWT) was first applied to patients in 1980 to break up kidney stones⁷⁾, and later it was successfully employed for many orthopedic diseases such as nonunion of long bone fracture⁸⁾, plantar fasciitis^{9, 10)}, calcifying tendinitis of the shoulder^{11, 12)}, and several inflammatory tendon diseases¹³⁾; myofascial pain syndrome^{14, 15)}; and treatment of spasticity. The mechanisms of how ESWT induces the healing process in human tissue remain uncertain, but recent studies suggest that ESWT appears to involve a cascade of interaction between physical shock wave energy and biologic responses including the expression of angiogenesis-related growth factors such as eNOS (endothelial nitric oxide synthase), VEGF (vessel endothelial growth factor), and PCNA (proliferating cell nuclear antigen) and neovascularization^{16–19)}. The indications for ESWT in orthopedic disorders continue to expand¹³⁾.

Recently, clinical trials have been performed to evaluate the efficacy of ESWT. However, each study adopted different clinical scales that were insufficient to draw a definite conclusion about the efficacy of ESWT in reducing spas-

ticity after brain injury. To suggest a firm conclusion, we searched for studies published up to June 2013 and meta-analyzed the efficacy of ESWT in reducing spasticity after brain injury.

SUBJECTS AND METHODS

We searched PubMed, TCL, Embase, and Scopus from their inception dates through June 2013 to identify interventional studies using ESWT to improve spasticity in patients with brain lesion. First, we searched PubMed and TCL records using the following criteria: ((Muscle OR Muscular) AND (Spastic* OR Hypertonia* OR Hypertonicit*)) OR (Muscle Tone Increased OR Spasticity) AND (Shock Wave* OR ESWT). Second, we searched Embase using the following criteria: (muscle hypertonia'/exp OR (muscle OR muscular AND (spastic* OR hypertonia* OR rigidit*)) OR (muscle AND tone AND increased) OR spastic*) AND (shock wave'/exp OR shock wave* OR 'ESWT'). Third, we searched Scopus using the following criteria: ((muscle OR muscular) AND (spastic* OR hypertonia* OR rigidit*)) AND (shock wave* OR "ESWT"). Seventy-three studies were retrieved. Two reviewers working independently screened all the abstracts and the titles for the candidate studies and discarded the studies in which extracorporeal shock waves were used for different purposes other than spasticity. After the initial screening, they reviewed the full text publications for eligibility, and disagreements between the two reviewers were resolved by consensus. Only studies written in English were selected.

All of the studies using ESWT for the purpose of ameliorating spasticity in patients with any brain injury were included. The studies involving other concomitant interventional procedures, such as botulinum toxin injection, were excluded. We included the studies that provided both baseline and postprocedure Modified Ashworth Scale (MAS) grades for selected muscles. The MAS grade was assessed immediately after application of ESWT in all included studies. Among them, four studies suggested MAS grade which was assessed 4 weeks after application of ESWT. The MAS grade ranged from 0 to 4, with 0 indicating no increase in muscle tone and 4 indicating rigid in flexion and extension.

From the selected studies, we abstracted data regarding follow-up durations, pre- and postprocedure MAS grades, and MAS grades at four weeks after ESWT, and compared them between time intervals.

MAS grades were statistically analyzed. Mean $\pm$ standard deviation values for pre- and postprocedure MAS grades and for the MAS grades at four weeks after ESWT were provided in all studies. Heterogeneity refers to the differences between studies in terms of methodological factors, such as use of blinding and concealment of allocation. Significant statistical heterogeneity arising from methodological diversity or differences in outcome assessments suggests that the studies are not all estimating the same quantity but does not necessarily suggest that the true intervention effect varies. A number of options are available if statistical heterogeneity is identified among a group of studies that would otherwise be considered suitable for a meta-

analysis²⁰. Heterogeneity was calculated by the Cochrane Q statistic test and the I^2 test²¹. The I^2 test describes the rate of variation across studies due to heterogeneity rather than chance and ranges from 0 (no heterogeneity) to 100 (maximum heterogeneity). All results are reported with 95% confidence intervals (95% CI), and all p-values are two-tailed. When a significant heterogeneity among the outcomes was found ($I^2 > 50$), the random effects model according to DerSimonian-Laird was used²². This model assumes that the true treatment effects in individual studies may be different from one another and that these treatment effects are normally distributed. Those outcomes that did not present with heterogeneity ($I^2 < 50$) were analyzed with the fixed-effects model. The fixed-effects model uses the inverse variance approach, and it is assumed that all studies come from a common population. Subgroup analysis was also used to detect heterogeneity according to the muscle groups assessed in each study. The MAS grades assessed immediately after ESWT ($I^2 = 0.0\%$) and 4 weeks after ESWT ($I^2 = 0.0\%$) were analyzed by the fixed-effects model. Because of the small number of studies in each subgroup, we used a funnel plot, Begg's test, and Egger's test simultaneously to detect publication bias. Begg's and Egger's tests are recommended when there is insufficient evidence²³. The analysis was performed using Comprehensive Meta-Analysis version 2.0 (Biostat, Englewood, NJ, USA).

RESULTS

The primary search for the effect of ESWT on spasticity in patients with brain injury identified 73 relevant studies, and 32 duplicate studies were discarded. Thirty-four studies were excluded after screening of their abstracts. Two studies were additionally excluded: one study used botulinum toxin injection before application of ESWT, and the other study presented insufficient data for meta-analysis. Ultimately, five studies were included in the meta-analysis. Four studies examined the spasticity of the ankle plantar flexor, and one study examined wrist and finger flexors (Table 1, Fig. 1). For quality assessment of the studies included in this meta-analysis, the Newcastle-Ottawa Scale was used (Table 2). The characteristics of the intervention and relevant outcome measurements for each study are described in Table 3.

Five studies assessed the effects of ESWT on improvement of the MAS grade immediately after application of ESWT. Six groups from 5 studies were evaluated. The MAS grade was significantly improved after ESWT compared with the baseline values (standardized mean difference [SMD], -0.792 ; 95% CI, -1.001 to -0.583 ; $p < 0.001$) (Fig. 2). Significant inter-study heterogeneity was not found ($\chi^2 = 2.53$, $p = 0.77$, $I^2 = 0.0\%$). Begg's test ($p = 0.09$) and Egger's test ($p = 0.06$) suggested that some bias source might be included in this sample of studies, but the classic fail-safe N was 83. Therefore, we concluded that the selected studies were not biased. Funnel plot analysis was also performed (Fig. 3A). We also performed a subgroup analysis based on the tested muscles, and it did not show any different results (Fig. 4A).

The MAS grade was also assessed four weeks after ap-

plication of ESWT. Five groups in 4 studies were evaluated. The MAS grade was significantly improved after ESWT compared with the baseline values (standardized mean difference [SMD], -0.735 ; 95% CI, -0.951 to -0.519 ; $p < 0.001$) (Fig. 5). Significant inter-study heterogeneity was not found ($\chi^2 = 4.706$, $p = 0.319$, $I^2 = 14.994\%$). Begg's test ($p = 0.05$) and Egger's test ($p = 0.009$) suggested that some bias source might be included in this sample of studies. However, the

classic fail-safe N was 59. Therefore, we concluded that the selected studies were not biased. Funnel plot analysis was also performed (Fig. 3B). We also performed a subgroup analysis based on tested muscles, and it did not show any different results (Fig. 4B).

DISCUSSION

Spasticity, as defined by Lance in 1980, is a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes ("muscle tone") with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of upper motor neuron syndrome²⁴. The pathophysiology of spasticity and hypertonus is complex and not clearly understood yet. Different spinal and supraspinal pathways contribute to it, and multiple neuronal mechanisms lead to increased reflex excitability. Even though spasticity and hypertonus provide some benefits to patients²⁵, most of the result of the spasticity may be detrimental. Spasticity can cause discomfort and stiffness and

limitations in physical activities such as walking, transferring, picking up objects, washing, dressing, or sexual activity²⁶). Four of the studies included in this meta-analysis evaluated the reduction of spasticity in ankle plantar flexors because it has a major functional implication in gait in patients with cerebral palsy or stroke²⁷⁻³⁰). Poorly managed

spasticity of the plantar flexors is responsible for muscle shortening and the development of tendon and soft tissue contractures, leading to an impaired swing phase of gait. One of the studies evaluated spasticity of wrist and finger flexors in patients affected by stroke because it may seriously impair hand functions and activities of daily living³¹).

A number of pharmacological agents and non-pharmacological treatments such as physical therapy, orthoses, and transcutaneous electrical nerve stimulation (TENS) have been tried for the treatment of spasticity and hypertonus³². Chemodenervation also called neurolysis or neuromuscular blockade are used to prevent nerve-muscle transmission with perineural injection of phenol^{33, 34}) or ethyl alcohol³⁵) and intramuscular injection of botulinum toxin^{36–41}). More invasive treatment options such as rhizotomy^{42–44}) and intrathecal baclofen^{45–48}) could be another choice for patients who are resistant to conventional treatments or have intractable spasticity. Treatment of spasticity needs to be performed with a stepped care approach that begins with simple and reversible treatments that have few side effects and proceeds to irreversible treatments that have more side effects.

Botulinum toxin injection has been tried in many studies and proven to be effective on improving muscle spasticity^{36–41}). However, the efficacy of botulinum toxin injection has been challenged by several reasons. The formation of neutralizing antibodies after botulinum toxin injection happens in more than one-third of dystonic patients who are labeled as “nonresponders”⁴⁹). Other reasons for the lack of response to botulinum toxin injections are inappropriate dosing, changes in the pattern of muscle involved, incorrect injection sites, reconstitution, and/or storage failure⁵⁰).

The indications for ESWT, which was first applied for lithotripsy⁷), have expanded to a variety of orthopedic diseases over the last decades. Two different mechanisms of the effect of ESWT are noted; one mechanism of effect is the high positive pressure and short rise time, which are responsible for the direct shock wave effect, and the other is the tensile wave for the cavitations, which is called the indirect shock wave effect⁵¹). However, the mechanism of how the ESWT affects spasticity remains uncertain. Nitric oxide has a very important physiological function in the central nervous system and in the transmission of the nerve impulse in the neuromuscular junction⁵²). A number of studies have investigated the effect of ESWT by inducing enzymatic and nonenzymatic nitric oxide synthesis^{17, 53}). Although, it has been suggested that nitric oxide plays an important role in regulating inflammatory events, biomechanical mechanisms underlying these effects have yet to be elucidated¹⁹).

Although the etiology of spasticity is central, secondary changes in peripheral nerves and muscles are critical factors in producing spasticity. Therefore, most of therapeutic interventions are focused on these secondary changes. There are structural and functional changes in spastic skeletal muscle. Most published micrographs of muscle from spastic patients showed abnormalities such as increased fiber size variability, increased number of rounded fibers, moth-eaten fibers, and increased extracellular space. In

addition, spastic muscles present increased joint stiffness, and this is presumably due to fibrosis within the muscle tissue or an increase in the number of crossbridges attached during contraction. Moreover, muscle contractures occur secondary to spasticity due to a reduction in muscle fiber length and a decrease in the number of serial sarcomeres within muscle fibers⁵⁴). One possible effect of ESWT is the improvement in connective tissue stiffness acting on fibrosis of chronic hypertonic muscles. These considerations are consistent with recent studies assessing the advantages of ESWT for several orthopedic and traumatic indications including problematic soft tissue wound^{55–57}).

When analyzing the results of ESWT for treatment of spasticity and hypertonus, adopting a reliable method for assessing spasticity is challenging. The Ashworth scale, first developed in 1964⁵⁸), is the best known scale for measuring the degree of spasticity²⁶). Among the clinical evaluation tools, the MAS which has a good interrater reliability, was adopted for comparing pre- and posttreatment changes in severity of spasticity in this meta-analysis. The meta-analysis indicated that ESWT improved the MAS grade significantly compared with the baseline values. In all studies, the MAS grade decreased in a statistically significant manner at the time immediately after ESWT and at four weeks after ESWT, and the SMDs and 95% CIs were -0.792 and -1.001 to -0.583 ($p < 0.001$) and -0.735 and -0.951 to -0.519 ($p < 0.001$), respectively.

There were some limitations to this study. The MAS, even though it is the most frequently cited rating scale for measurement of spasticity, does not evaluate the velocity of passive joint movement and the angle of contraction outbreak or potential tendon retraction^{59, 60}). Also, even if this scale seems to measure the resistance adequately, the reduced range of joint motion due to contracture might limit its reliability⁶¹).

Therefore, the MAS does not substantially reflect spasticity according to Lance’s definition, that is, a motor disorder characterized by a velocity-dependent increase in muscle tone²⁴). On the other hand, the Modified Tardieu Scale does take into account the velocity of passive joint movement and assess the angle of catch and the speed at which the catch was obtained forms the basis of the measure of spasticity. In addition, the Modified Tardieu Scale is more sensitive in the detection of posttreatment changes because it measures muscle resistance as well as the velocity of the movement that induces muscular contraction⁶²).

Another limitation of the present study was that the MAS does not include clinical features including pain, spasm, and impact of function that could be associated with spasticity. The clinical impacts of spasticity that discourage patients include spasm or pain accompanied by hypertonicity; functional deterioration of activities of daily living such as walking, transferring, dressing and washing; and burden placed on caregivers. Therefore, other clinical assessment scales such as the visual analogue scale (VAS) for pain assessment, spasm frequency scale (SFS) or clonus score, daily functional assessment scales, and patient/caregiver goal assessment scale should be included in future studies.

A third limitation is the short follow-up periods in the

included studies. The average follow-up duration was only 4 weeks in two studies and was 12 weeks in two other studies; the final study evaluated immediate effects of ESWT only. Therefore, it is difficult to suggest the optimal treatment interval from this meta-analysis. Long-term follow-up studies are needed in future studies.
