Fatigue Failure by Flow-Induced Vibration*
(Effect of Initial Defect Size on Cumulative Fatigue Damage)

Satoru ODAHARA**, Yukitaka MURAKAMI***, Masahiro INOUE** and Atsuo SUEOKA***

A fatigue life prediction method is presented based upon the data obtained due to flow-induced vibration. In the experimental program a small wind tunnel was used to produce flow-induced vibrations of a Styrofoam cylinder. These vibrations were transmitted to an attached fatigue specimen. The specimen was made of a medium carbon steel with a small hole drilled into its surface to simulate a defect and to localize the fatigue crack propagation process. A small portable strain histogram recorder (Mini Rainflow Corder, MRC) was used to acquire the service strain histogram and also to measure the variation of natural frequency. Fatigue damage, $D$, was defined by the Modified Miner’s Rule and was determined by using the strain histogram of the early portion of the test record. The values of $D$ were all smaller than 1.0 and ranged from 0.2 to 0.8. The effect of the size of the simulated defect on the values of $D$ was clarified by focusing on the relationship between small crack growth behavior and the strain histogram.

**Key Words:** Flow-Induced Vibration, Fatigue Life Prediction, Cumulative Fatigue Damage, Mini Rainflow Corder, Modified Miner Rule, Initial Defect Size, Fatigue Limit, Over-Strain Frequency Ratio, $\sqrt{area}$ Parameter Model, Critical Crack Initiation Stress from a Crack

1. Introduction

Interest in the consequences of flow-induced vibration was stimulated by an accident which occurred in the fast breeder reactor, MONJU on 8th December 1995(1). The accident was caused by a fatigue failure resulting from the flow-induced vibration of a thermocouple well installed in the piping of secondary cooling system which resulted in the leakage of liquid sodium(2). Subsequently, a number of other flow-induced fatigue failures have been reported(3), (4). The design of wind turbine blades also involves the analysis of fatigue resistance under flow-induced vibration. Although it is difficult to predict fatigue strength and fatigue life in the case of wind turbine blades because of the complex shape of wind turbine blades and the variation of flow conditions(5), (6), nevertheless it is important to work toward the establishment of an overall procedure for preventing fatigue failure due to flow-induced vibration.

The analysis of the phenomenon of fatigue failure by flow-induced vibration requires a multi-disciplinary approach involving aspects of strength of materials, fluid dynamics and mechanical vibrations(7), (8). In our previous studies the conditions for exciting flow-induced vibration were analyzed, and a small wind tunnel to induce fatigue failure by flow-induced vibration was constructed. In order to detect fatigue cracks in an early stage we paid particular attention to three parameters: (1) the variation of displacement amplitude of the specimen system, (2) the variation in natural frequency, (3) and the variation of the strain histogram at the anticipated crack initiation site. The conclusions obtained were as follows: (1) the early detection of fatigue failure by variation of vibration amplitude of test cylinder and natural frequency with crack growth was difficult, because changes in vibrational amplitude and natural frequency were quite small for crack lengths less than 1.0 mm. However, it was possible to predict the symptoms of fatigue failure at crack lengths of 1.0 mm or more by monitoring the variation
of strain frequency distribution near the crack initiation site\(^{(7),(8)}\). Although it was difficult to predict the symptoms of fatigue failure by the measurement of mechanical vibrations, it is a useful technique for non-destructive inspection in that the symptoms of fatigue failure can be determined by means of measuring the variation of strain history near cracks for crack sizes in excess of 1 mm.

Since flow-induced vibration leads to cyclic loading which is random in nature, consideration must be given the matter of damage accumulation. For this purpose the Modified Miner Rule, a well-known linear summation of the fractions of cumulative fatigue damage based on the \(S-N\) diagram, is generally used for the prediction of fatigue life under variable amplitude loading. However in practice there is a wide scatter of in the value of the cumulative fatigue damage parameter \(D\). This variation in the value of \(D\) had been related to scatter in material properties and variation in the stress frequency distribution\(^{(9)}\). It has been also reported that the value of \(D\) depends on the characteristics of initial defects such as notches and holes\(^{(10),(11)}\). Kikukawa, Jono and Kondo\(^{(12)}\) have also shown that the value of \(D\) is influenced if a portion of the cycles are below the fatigue limit.

In the present study, the effect of the initial defect size on the value of \(D\) was clarified by focusing on the relationship between small crack growth behavior and the strain histogram under flow-induced vibration. A small wind tunnel\(^{(7),(8)}\) was used. The test cylinder was attached to a 0.47% carbon steel specimen and was mounted in the wind tunnel and flow-induced vibrations were induced. Various sized small holes were introduced onto the specimen surfaces. The MRC counts strain frequency using the Rainflow counting algorithm\(^{(15),(16)}\), and the analysis can be carried out with a PC. The maximum strain range which can be measured is \(7 \times 10^{-6}\), and the total range is divided into 256 levels. The minimum strain range, \(\Delta \varepsilon_{\text{min}}\), is approximately \(26 \times 10^{-6}\).

Cumulative fatigue damage \(D\) as defined by the Modified Miner Rule was evaluated by using the strain data obtained during the initial stage of test. The variation of the value of \(D\) is related to small crack growth behavior and is caused by various combinations and sequences of higher stress and lower stress on the basis of fatigue limit in relation to crack size at every moment\(^{(17)}\). The contribution of stresses below the fatigue limit to crack growth was determined on the basis of the critical crack initiation stress from the original crack as proposed by Murakami and Matsuda\(^{(18)}\). Additionally, a fatigue life prediction method based on the data at an early stage under flow-induced vibration is presented based on particular measurements and observations. This method is expected to be applicable to the fatigue life evaluation for a variety of machines and structures under flow-induced vibration, such as wind turbine generator, nuclear power components, gas turbines, power transmission towers and traffic sign poles, for example.

### 2. Material and Specimens

The material used was a rolled 0.47% carbon steel turned after annealing at 844°C for 1 hr. The chemical composition was (mass %) 0.47C, 0.21Si, 0.82Mn, 0.018P, 0.018S, 0.01Cu, 0.018Ni and 0.064Cr. The mechanical properties were 621 MPa tensile strength, 339 MPa lower yield strength, 1104 MPa true fracture strength and 53.8% reduction of area. Figure 1 shows the shape and dimensions of the hour-glass shaped specimen. The minimum diameter of the specimen was 3.3 mm. The specimen surface was finished with emery paper and buffed. The specimens contained a drilled small hole of either 40, 100 or 200 \(\mu\)m diameter at the minimum cross section of specimen. The diameter of \(d\) of the hole and its depth \(h\) were identical. Specimens were then annealed in a vacuum at 600°C for 1 hour to relieve residual stress caused by drilling. The Vickers hardness after vacuum annealing was \(HV = 176\) which is a mean value of each specimen measured at 4 points with 0.98 N loading. The scatter in \(HV\) was within 4%.

### 3. Experimental Equipment and Experimental Method

#### 3.1 Experimental equipment

Figure 2 shows the configuration of the small wind
This wind tunnel consists of a bell mouth, an acrylic section attached to a wooden section (400 × 400 mm in cross section) and a suction fan. The suction fan was equipped with a lattice net attached at the entry of the fan in order to reduce the swirl velocity and to obtain uniform flow around the test cylinder. Figure 3 shows the test cylinder which consists of a core cylinder of (a) 0.45% C steel or (b) aluminum partially covered with a Styrofoam cylinder and polyurethane, a specimen and a base. The test cylinder system was fixed at the center of the acrylic section. The base was made of 0.45% carbon steel is 17 times heavier that the test cylinder so as not to cause induced resonance. The flow velocity \( U \) can be varied from \( U = 0 \) m/s to 12.6 m/s. In order to keep \( U \) constant during test run, the windows in the laboratory were kept either open or closed to minimize any possible variation in air pressure.

### 3.2 Test procedure and experimental conditions

Figure 4 shows the test procedure. In the continual flow-induced tests, the measurements were made at every 30 min from start of a test until specimen failure occurred. The strain histogram was determined by the MRC for the last 5 minutes of an every 30 minute measurement block. The vibrational amplitudes of the test cylinder were recorded over a 1 minute period by a video camera which was mounted at the top of the wind tunnel. After each 30 minute run, a replica of the fatigue crack was made, and its length was then determined with an optical microscope.

The Strouhal number, \( S \), controls the conditions of flow-induced vibration. According to experimental research\(^{(19), (20)}\), \( S \) must be within a specific range to obtain flow-induced vibration. \( S \) is defined by

\[
S = f_s D_c / V
\]

where \( f_s \) is vortex shedding frequency in Hz, \( D_c \) the diameter of test cylinder in m, \( V \) flow velocity around test cylinder in m/s. In practice it is difficult to measure the vortex shedding frequency \( f_s \) by means of observation of vortex shedding behind the test cylinder. However, since self-excited vibration with vortex shedding is caused when the \( f_s \) is almost identical to the natural frequency \( f_n \) of a cylinder\(^{(19), (20)}\), in the present study, \( f_n \) was adopted instead of the \( f_s \) in the calculation of \( S \). \( V \) is the modified free flow velocity, \( U \), based on the continuity equation at the test cylinder in the cross section of acrylic tube.

Figure 5 shows the relationship between the Strouhal number \( S \) and the vibrational amplitude of a cylinder. It is noted that the vortex pattern changes as the Strouhal number \( S \) increases. In domain No.1 \( S \) ranges from 0.10 to 0.22, and vibration transverse to flow direction. In domain No.2, \( S \) ranges from 0.33 to 0.40, and vibration parallel to the flow direction occurs with alternating vortex shedding. In domain No.3 \( S \) ranges from 0.40 to 0.83, and vibration parallel to flow direction is caused with symmetrical vortex shedding. The conditions present the time of the of “MONJU” accident were \( f_n = 265 \) Hz, \( D_c = 0.01 \) m, \( U = 5.0 \) m/s, \( S = 0.53^{(2)} \), corresponding to domain No.3. However, limitations of the laboratory equipment limited the test conditions to domain No.1. In the present study, a value of the Strouhal number, \( S \), of 0.15 was adopted to obtain the largest amplitude of test cylinder. The conditions leading to fatigue failure within a short time were
found in preliminary tests in which several dimensions and masses of test cylinders and specimens, and flow velocity was examined. The flow velocity was determined to provide a fixed shape to the strain histogram. The final test conditions were: \( f_a = 15.8 \text{ Hz}, \ D_c = 0.15 \text{ m}, \ V = 16.1 \text{ m/s}, \ S = 0.15 \).

Figure 6 (a) shows that the vibrational amplitude trace of a reference point on the top of test cylinder during a 1.0 minute test run. It is evident that due to alternating vortex shedding, the direction of vibration of the cylinder was almost perpendicular to the flow direction, as expected. Figure 6 (b) shows a fatigue crack emanating from a small hole of diameter, \( d \), equal to 40 µm. The crack length, \( l \), which includes the diameter of the hole, was 786 µm after \( N = 1.3 \times 10^6 \) reversals. It is evident that the crack propagation was almost perpendicular to the axis of specimen. Figure 7 shows the position of the strain gauge which was used to monitor the nominal strain. The strain gauge was attached to a specimen at a position diametrically opposite to the small hole.

4. Results and Discussion

Since vortex shedding behavior, vibrational amplitude and natural frequency all vary with crack growth, the determination of the crucial factors controlling such a complex coupled problem before a flow-induced vibrational fatigue test is difficult. Instead we approach the fatigue process due to flow-induced vibration in a different manner by monitoring the variation of the three following parameters with crack growth at every moment: (1) the variation of the displacement amplitude of the test cylinder, (2) the variation of natural frequency, (3) the variation of the strain histogram at a critical point on the specimen. However, since in the previous study \( (7), (8) \) the variation of displacement amplitude of the test cylinder hardly changed until final failure, therefore in the present study particular attention was given to the variation of natural frequency and the variation of the strain histogram at a critical point of the specimen during fatigue crack growth.

4.1 Variation of natural frequency

First of all, the variation of natural frequency with crack growth was investigated. The natural frequency is defined from the strain frequency over a 5 minute measurement by the MRC. In the case of the algorithm for the Rainflow cycle counting method, the number of reversals \( N \) is two times the number of ordinary cycle counts \( (15), (16) \). Thus the natural frequency \( f_a \) [Hz] was defined as

\[
f_a = \frac{\text{Strain frequency measured by MRC for 5 min}}{2} \times 60 \text{ sec} \tag{2}
\]

Figure 8 shows an example of the relationship between variations of natural frequency \( f_a \) [Hz] and crack length \( l \) [µm] as function of the number of reversals, \( N \). The left ordinate indicates the natural frequency \( f_a \) and the right ordinate indicates the crack length \( l \) in logarithmic scales, and the abscissa indicates number of reversals \( N \). The experiment test conditions were: \( f_{a0} = 15.8 \text{ Hz}, \ D_c = 0.15 \text{ m}, \ V = 16.6 \text{ m/s}, \ S = 0.147 \). It is noted that \( f_{a0} \) is the natural frequency at the initial stage of test with no crack. A detectable crack initiated at the edge of the hole at \( N_i = 1.1 \times 10^5 \) reversals and the specimen failed at \( N_f = 1.5 \times 10^6 \) reversals. Note that as expected the natural frequency \( f_a \) hardly varied until final failure. Additionally, as discussed at the following section, the reduction ratio of \( f_a \) at final failure differs for the several experimental conditions. Therefore, as discussed in the previ-
Fig. 8 Variation of natural frequency and crack growth. $f_{n0}$: Natural frequency at the first stage of test, $V$: Flow velocity, $D$: Diameter of test cylinder, $S$: Strouhal number, $N_i$: Reversals to crack initiation, $N_f$: Reversals to failure.

Fig. 9 Strain histograms of strain frequency for 5 min measurement at various crack length. $N$: Number of reversals. Diameter of small hole is 40 $\mu$m.

Fig. 10 The mean value of the strain range and the crack length as functions of the number of reversals.

where $\Delta \varepsilon_i$ is the individual strain level made by dividing $7\times10^{-6}$ into 256 levels, $n_i$ is the strain frequency (reversals) for a 5 minute measurement and $N_{f\text{max}}$ is the total frequency (reversals) for a 5 minutes measurement. Figure 10 shows the relationship between the mean value of strain range $\Delta \varepsilon_m$ as defined by Eq. (3) and the crack length $l$. It is evident that the $\Delta \varepsilon_m$ remained almost constant with crack growth. The fact that the strain histogram and the $\Delta \varepsilon_m$ at the initial stage of test hardly varied until crack grew up to $l=1.0$ mm holds even in the case of other experimental conditions. Therefore, as discussed at the following section, no change of strain histogram until a crack grows up to $l=1.0$ mm also becomes a significant guideline for the evaluation of fatigue life by using the strain data at the first stage of test.

4.3 Fatigue life evaluation by using the data at an early stage

Service loading under flow-induced vibration is random, so that it is difficult to predict the service stress and strain analytically in the design stage. Therefore, it is necessary to measure the actual strains to develop a method for the precise prediction of the fatigue life under flow-induced vibration. In the present study the method of fatigue life evaluation is based on the data at an early stage before a crack is detected.

4.3.1 Cumulative fatigue damage based on the Modified Miner Rule

The cumulative fatigue damage, $D$, based on the Modified Miner Rule measured from the start of a test to the $k$-th measurement block was calculated only for first 30 minute strain measurement period. The value of $D$ is therefore defined as

$$D = \sum_{j=1}^{k} \left( \frac{n_{ij}}{N_{fi}} \times \frac{30\text{ min}}{5\text{ min}} \right)$$

where $k$ is the sequence number of the measurement block, $n_{ij}$ frequency of individual strain level in 256 divided levels of $7\times10^{-6}$ for 5 min at the first 30 min measurement, $N_{fi}$ is fatigue life (reversals) for individual strain level $\Delta \varepsilon_i$. $N_{fi}$ for the same material containing a small
S-tending the Miner Rule, the imaginary fatigue lives, obtained by extending Eqs. (5) and (6). In order to adopt the Modified Miner Rule, the imaginary fatigue lives, obtained by extending the S-N diagram below the fatigue limit \( \sigma_n \) calculated by the following Eq. (10), are indicated by broken lines.

\[
\Delta \varepsilon = \Delta \sigma / E = 1.23 \times 10^3 \cdot \Delta \sigma_p^{0.26}
\]

(6)

\[
\Delta \varepsilon_i = \Delta \varepsilon_f + \Delta \varepsilon_p
\]

(8)

By substituting Eq. (6) to Eq. (7), \( \Delta \varepsilon_c \) becomes a function of \( \Delta \varepsilon_p \). Thus, \( \Delta \varepsilon_i \) is a function of \( \Delta \varepsilon_p \) from Eq. (7) and Eq. (8). \( \Delta \varepsilon_i \) is identical with respective strain levels \( \Delta \varepsilon_i \) measured by MRC. On the basis of the non-linear equation \( \Delta \varepsilon_i = \Delta \varepsilon_p + 1.23 \times 10^3 \cdot \Delta \sigma_p^{0.26} / E, \Delta \sigma_p \) which corresponds to \( \Delta \varepsilon_i \) can be obtained by numerical calculation. Young's modulus measured by tensile test was \( E = 210 \) GPa.

Figure 11 shows the S-N curves based on the Manson-Coffin law. The abscissa is the number of cycles to failure \( N_f \) and the ordinate is the stress amplitude \( \Delta \sigma / 2 \). It should be noted that the ordinate is on logarithmic scale. Respective curves were calculated with the relationship between Eqs. (5) and (6). In order to adopt the Modified Miner Rule, the imaginary fatigue lives, obtained by extending the S-N diagram below the fatigue limit \( \sigma_n \) calculated by the following Eq. (10), are indicated by broken lines.
mined as the stress above and bellow fatigue limit, are defined as to vary with increase in crack size. In addition, over-strain is defined as strain range corresponding to over-stress and under-strain is defined as strain range corresponding to under-stress.

4.3.2 Effect of under-stress frequency below fatigue limit on the value of $D$  
In order to evaluate the effect of under-stress below the fatigue limit on the scatter of the value of $D$, the over-stress frequency ratio $\eta$, which is the ratio of over-stress frequency to total frequency for 5 min, was defined as follows.

$$\eta = \sum_{i=1}^{256} n_i (\Delta \varepsilon_i > \Delta \varepsilon_w) / N_{5 \text{min}}$$  \hspace{1cm} (9)

where $n_i (\Delta \varepsilon_i > \Delta \varepsilon_w)$ is the over-stress frequency in the first measurement for 5 min, $N_{5 \text{min}}$ is total frequency (reversals) for 5 min measurement. The value of $\eta$ was defined at the initial stage of test with no crack.

Figure 13 shows the variation of flow-induced vibration traced by a mark at the top of the test cylinder recorded by the video camera under an experimental condition $f_{so} = 10.8$ Hz, $D_c = 0.15$ m, $V = 10.2$ m/s, $S = 0.16$. The wave was recorded at the first 30 min with no crack. The abscissa is number of reversals and theordinate is the displacement of the mark at the top of the test cylinder. Although the test cylinder vibration is random, it seems that the mean value of vibration wave is almost zero. Therefore, it was assumed to be that a mean stress $\sigma_m$ equals zero. Additionally, it was found that the mean stress $\sigma_m$ was almost zero for the case of other experimental conditions by means of the trace of the mark of test cylinder.

The prediction method of fatigue limit based on the $\sqrt{\text{area}}$ parameter model for the case that the mean stress $\sigma_m$ equals to zero\(^{(22)}\) is expressed as:

$$\sigma_w = 1.43 (HV + 120) / \left( \sqrt{\text{area}} \right)^{1/6}$$  \hspace{1cm} (10)

where $\sigma_w$ is the predicted fatigue limit in MPa, $HV$ is Vickers hardness in kgf/mm\(^2\), $\sqrt{\text{area}}$ is the square root of the area occupied by projecting defects or cracks onto the plane normal to the maximum tensile stress in $\mu m$. In the case of this material, fatigue limit can be predicted within ±10% error by using Eq. (10)\(^{(22)}\). It must be noted that $\sigma_w$ are functions of crack size, and accordingly the values of $\sigma_w$ are not determined by the initial condition of specimen but vary at every moment with the variation of crack size, i.e., crack propagation. Additionally, over-strain and under-strain on the basis of the fatigue limit should be also considered to vary with crack growth at every moment.

The calculation of strain range corresponding to the fatigue limit $\Delta \varepsilon_w$ for the case of diameter of small hole $d = 100$ $\mu m$ was attempted as follows. The fatigue limit $\sigma_w$ is $\sigma_w = \Delta \varepsilon/2 = 199$ MPa by Eq. (10) for the case of diameter of small hole $d = 100$ $\mu m$ and $HV = 176$. The plastic strain range corresponding to the fatigue limit $\Delta \varepsilon_{mp}$ is calculated as $\Delta \varepsilon_{mp} = (\sigma_w / 1230)^{1/0.26} = 907 \times 10^{-6}$ by using Eqs. (6) and (10). The plastic strain range $\Delta \varepsilon_p$ is represented as $\Delta \varepsilon_p = 2 \sigma_w / E$. Eventually, $\Delta \varepsilon_{mp}$ becomes $\Delta \varepsilon_{mp} = (\sigma_w / 1230)^{1/0.26} + 2 \sigma_w / E = (199 / 1230)^{1/0.26} + 199 / (120 \times 1000) = 2.799 \times 10^{-6}$.

In the previous study\(^{(7),(8)}\), the value of $D$ was defined as the cumulative fatigue damage at final failure. However, as shown by Table 2 the reduction ratio of natural frequency for crack length $l = 3$ mm to natural frequency at the initial stage with no crack, $(f_{so} - f_{n>3 \text{mm}})/f_{so}$, depends on experimental condition such as Strouhal number $S$, flow velocity $V$, cylinder mass $m$ and diameter of cylinder $D_c$. Therefore, it is difficult to predict the value of $D$ at failure by using only the strain data in the first stage of test, because crack growth up to $l = 3$ mm depends on the variation of natural frequency. On the other hand, as aforementioned the natural frequency and strain histogram in the first stage of a test hardly changed until crack grew up to $l = 1.0$ mm. Additionally, the crack propagation life until crack length $l = 1.0$ mm occupied almost the whole life\(^{(22)}\). Moreover, it is realized that crack growth up to $l = 1.0$ mm occupied almost the whole life even in the case of the larger diameter hole in a specimen than the one in the present specimen. This is easily confirmed from a viewpoint of the crack propagation law.

*JSME International Journal*
Therefore, the value of $D$ was determined as the fatigue damage at crack length $l=1.0$ mm. Thus, $k$ was defined as the sequence number at the crack length $l=1.0$ mm in Eq. (4).

Figure 14 shows the relationship between over-strain frequency ratio $\eta$ defined by Eq. (9) and fatigue damage $D$ at crack length $l=1.0$ mm defined by Eq. (4) based on the above calculation. The value of $D$ ranged approximately from 0.2 to 0.8 for the value of $\eta$ and the size of the small defects i.e. diameter of small hole, $d$. Judging from a trend in Fig. 14, two important conclusions may be drawn. The first is that the value of $D$ decreases with the decrease in over-strain frequency ratio $\eta$. Because the calculation of the value of $D$ based on the Modified Miner Rule is mainly dominated by the over-strain frequency above the $\Delta \varepsilon_w$ (17). The second is that the value of $D$ decreases with the increase in initial defect size, i.e. diameter $d$ of small hole. The reason why the values of $D$ depend on the initial defect size was explained, as discussed at following sections, by the relationship between the behavior of crack growth and the degree of contribution of under-strain below the $\Delta \varepsilon_w$ to crack growth.

Therefore, we can predict the variation of the value of $D$ on the basis of the relationship between over-strain frequency ratio $\eta$ and initial defect size by referring to Fig. 14. In other words, fatigue life prediction based on the Modified Miner Rule is mainly illustrated as the data at the first stage with no crack were assumed to have the same over-strain frequency ratio $\eta$. Strain histograms at the first stage with no crack were constructed to have the same over-strain frequency ratio $\eta$ and initial defect size i.e. diameter $d$ of small hole. Strain histograms in Fig. 15 were schematically illustrated as the data at the first stage with no crack were assumed to have the same over-strain frequency ratio $\eta$. It must be noted that the strain histograms in Fig. 15 were schematically illustrated as the data at the first stage with no crack were assumed to have the same over-strain frequency ratio $\eta$. Thus, the configuration does not mean that the strain histogram varies with crack growth under a constant experimental condition. In order to identify the strain range level which plays a different role for crack growth, the domains of strain frequency at the different level were classified as follows.

area A : The domain of strain frequency above the $\Delta \varepsilon_w$ area B : The domain of strain frequency below the $\Delta \varepsilon_w$ and above the $\Delta \varepsilon_{ui}$ area C : The domain of strain frequency below the $\Delta \varepsilon_{ui}$

Under constant amplitude loading, if the strain range is in area A, a specimen fails; if the strain range is in area B, even though a crack initiates from an original crack, the crack does not propagate; if the strain range is in area C, a
crack does not initiate. However, under variable amplitude loading, the area B shifts to the small strain range with crack growth, and the strain range at the area C also can contribute to crack growth developed by the frequency of strain range at area A and area B. The increase in the size of initial defect. That is, under-size. Therefore, as shown by Fig. 15, area B which is in MPa, contributes to the critical crack initiation stress from a crack was derived from the following.

According to the experimental research of Murakami and Matsuda\(^{16}\), it was found to be that threshold effective stress intensity factor range \(\Delta K_{eff,th}\) was not dependent on the small crack size, but kept almost constant from 100 \(\mu\)m to 1 000 \(\mu\)m\(^{18}\). Thus, \(\Delta K_{eff,th}\) was derived:

\[
\Delta K_{eff,th} \equiv 3.4-3.6 \text{MPa-m}^{1/2}
\]

(0.46\% C annealed steel) (11)

On the other hand, the maximum value of the stress intensity factor along the front of a three-dimensional crack (Mode I)\(^{23}\) is given approximately by:

\[
K_{l,max} \approx 0.650\sigma_0 \sqrt{\pi \text{area}}
\]

(12)

where \(K_{l,max}\) is in MPa-m\(^{1/2}\), \(\sigma_0\) is stress amplitude for stress ratio \(R = -1\) in MPa, \(\text{area}\) is the square root of the area occupied by projecting defects or cracks onto the plane normal to the maximum tensile stress in m. The relationship \(\Delta K_{eff,th} = 2K_{l,max,th}\), which proved by using a numerical calculation based on the Dagdale model\(^{18}\), was used for the calculation of \(\sigma_{eff}\). By substituting \(K_{eff,th} = 3.4\text{MPa-m}^{1/2}\) for \(K_{l,max}\) and \(\sigma_{eff}\) for \(\sigma_0\) in Eq. (12), \(\sigma_{eff}\) is expressed as follows.

\[
\sigma_{eff} = 1.48 \times 10^3 / (\sqrt{\text{area}})^{1/2}
\]

(13)

where \(\sigma_{eff}\) is the critical crack initiation stress from a crack in MPa, \(\sqrt{\text{area}}\) is the square root of the area occupied by projecting defects or cracks onto the plane normal to the maximum tensile stress in \(\mu\)m. \(\sigma_{eff}\) can vary with increase in crack size at every moment. The conversion from \(\sigma_{eff}\) into \(\Delta \varepsilon_{eff}\) (strain range corresponding to \(\sigma_{eff}\)) was done by Eqs. (6)–(8) and Eq. (13). The critical crack initiation stress from the edge of the small hole may be larger than that from a crack, provided \(\sqrt{\text{area}}\) for the small hole was considered to be equivalent to that for the crack. In the present study it was assumed to be that the difference between \(\sigma_{eff}\) for a crack and \(\sigma_{eff}\) for a small hole was not large.

In the present material, \(\sigma_{eff}\) varies with the slope of \(-1/6\) and \(\sigma_{eff}\) varies with the slope of \(-1/2\) for the crack size. Therefore, as shown by Fig. 15, area B which is the shaded area at strain histograms becomes larger with the increase in the size of initial defect. That is, under-strain frequency below the \(\Delta \varepsilon_{eff}\), which contributes to crack growth, increases with increase in the size of initial defect. In the case of the diameter \(d = 200 \mu\)m of small hole the frequency area of the contribution of under-strain below the \(\Delta \varepsilon_{eff}\) to crack growth is larger than that in the case of the diameter \(d = 100 \mu\)m or \(d = 40 \mu\)m of small hole. The contribution of under-stress below the fatigue limit to the value of \(D\) is not large. Therefore, the value of \(D\) becomes much smaller as the initial defect size increases.

The fact that the value of \(D\) decreases with the increase in initial defect size can be schematically explained by focusing on the relationship between under-stress below the fatigue limit and crack growth on the basis of the critical crack initiation stress from a crack.

4.3.4 Correlations among variations of under-strain frequency below fatigue limit, the increase in the value of \(D\) and crack growth

For a clearer explanation of the effect of initial defect size on the value of \(D\), the relationship between the variation of under-strain frequency below the \(\Delta \varepsilon_{eff}\) with crack growth and the variation of crack size was monitored. Figures 16, 17 and 18 show correlations among the variations of area B with crack growth and fatigue damage curves. As described above, area B shaded at the strain histograms in Fig. 16 and in Fig. 17 are the domains between the \(\Delta \varepsilon_{eff}\) and the \(\Delta \varepsilon_{th}\). Although area B was defined at the initial stage with no crack for the case of explanation of Fig. 15, it must be noted that in the case of Figs. 16 and 17 area B on the basis of \(\Delta \varepsilon_{eff}\) and \(\Delta \varepsilon_{th}\) (which is functions of crack length \(l\)) vary with crack growth from initial defect size (to crack length \(l \approx 1.0 \text{mm}\)) at every moment. Over-strain frequency ratio \(\eta\) in Fig. 16 and that in Fig. 17 are almost alike. The effect of the difference between natural frequencies at the first stage of test, \(f_{\text{so}} = 9.5 \text{Hz}\) and \(18.2 \text{Hz}\), on crack growth was assumed to be negligible. The shape of strain histograms hardly changed with crack growth as shown in Fig. 9. In the calculation of \(\sqrt{\text{area}}\) with crack length \(l\), surface crack was assumed to be a semi-circle shape, that is, aspect ratio equals to unity. As above discussions, the contribution of under-strain frequency below the \(\Delta \varepsilon_{eff}\) to the value of \(D\) is not large in both histograms in Fig. 16 (a) and in Fig. 17 (a).

The difference of area B between Figs. 16 (a) and 17 (a) at the first stage of crack growth is distinct. In Fig. 17 \(d = 100 \mu\)m, area B is not large at initial stage and the increase in area B was not very large until crack grew up to \(l \approx 400 \mu\)m. As shown by Fig. 18, eventually the value of \(D\) at failure was \(D \approx 0.8\) for the case \(d = 100 \mu\)m. On the contrary, area B in Fig. 16 (a) is larger than the area in Fig. 17 (a) at the first stage of crack growth. Thus, as shown by Fig. 18, a crack growth shows a sharp rise with increasing in the value of \(D\) and specimen failed at \(D \approx 0.5\). The value of \(D\) based on the Modified Miner Rule calculated formally by the under-strain frequency below the \(\Delta \varepsilon_{eff}\) is not large. As the initial defect size is much larger, the contribution of the under-strain below the \(\Delta \varepsilon_{eff}\) to crack growth at the early stage of test becomes extensive. Therefore, as the size of initial defect is larger, the value of \(D\) at failure can become much smaller.
By means of monitoring the relationship between the variation of contribution of under-stress below fatigue limit on the basis of $\sigma_{wi}$ to the crack growth and the increase in the value of $D$ at every moment, it is possible to evaluate quantitatively the effect of initial defect size on the value of $D$. This experimental fact that the value of $D$ is affected by initial defect size is extremely significant to designing and maintenance of machines and structures under flow-induced vibration.

5. Conclusions

Fatigue failure by flow-induced vibration has caused a number of accidents, such as the leakage of liquid sodium at the fast breeder reactor, MONJU. It is therefore necessary to establish an integrated system for preventing the fatigue failures due to flow-induced vibration.
In the present study a fatigue life evaluation method based upon data obtained at an early stage of the fatigue life under flow-induced vibration conditions was developed. An experimental programs based upon experiment based on strength of materials, fluid dynamics and mechanical vibrations was conducted. The conclusions obtained can be summarized as follows:

(1) The natural frequency of the test cylinder and strain histogram at a critical point of the specimen hardly changed until crack grew up to 1.0 mm. This fact held even under every experimental condition.

(2) The fatigue damage $D$ based on the Modified Miner Rule and the strain histogram was determined for the initial stage of testing. The values of $D$ were less than unity under every test condition. The reason for the low values of $D$ is that flow-induced vibration includes stresses above and below fatigue limit.

(3) The value of $D$ at failure was defined as the fatigue damage at crack length $l = 1.0$ mm. The value of $D$ ranged approximately from 0.2 to 0.8 under several experimental conditions for various sizes small hole. In addition, over-strain frequency ratio $\eta$ was defined as the ratio of over-stress frequency above the fatigue limit to the total stress frequency during the initial stage of test before a detectable fatigue crack formed. It was found that $D$ decreased with the increase in over-strain frequency ratio $\eta$ and with increase in the size of the initial defect.

(4) By referring to the results at (3), it is possible to predict quantitatively the variation of the value of $D$ by using the relationship between the strain histogram at the first stage and initial defect size i.e. diameter of small hole on the basis of the $\sqrt{\text{area}}$ parameter model. Therefore, a fatigue life evaluation based on the data at the early stage is possible even under the condition of random amplitude loading such as flow-induced vibration, provided that the mean stress is close to zero.

(5) The reason why as the initial defect size increases the value of $D$ becomes much smaller is explained as follows: when the initial defect size is larger, the under-stress frequency below the fatigue limit contributes more extensively to crack growth in the early stage. The contribution of the under-stress frequency below the fatigue limit to the value of $D$ formally calculated by the Modified Miner Rule is not large. Consequently, the value of $D$ at failure becomes much smaller in the case that initial defect size is very large. The experimental fact that the value of $D$ is extremely affected by initial defect size is very significant in the practical assessment of the fatigue lives of machines and structures under flow-induced vibration.
