(Received 6 August 1996/Accepted 29 November 1996)

ABSTRACT. In order to clarify the pathogenesis of porcine serum (PS)-induced rat liver fibrosis, three experiments differing in dose of PS or duration of treatment were performed on male Fischer 344 rats. The rats were given an intraperitoneal injection of PS twice a week for 3 to 16 weeks and euthanized 7 days after the last injection for each treatment group. Liver tissues from these animals were subjected to detailed morphological and immunohistochemical examinations. Biochemical tests on treated rat serum revealed an increase in globulin concentration but no elevation in AST, ALT and ALP activities. There were no relationships among the dose of PS, the extent of fibrosis, and the anti-PS antibody titer. A number ofα-smooth muscle actin-positive non-myofibroblastic cells, desmin-positive cells, and lipofuscin-laden Kupffer cells were found around the central veins and in the fibrous septa. In advanced stages of fibrosis, a proliferation of elastic fibers were observed in the septa. These findings were considered to indicate gradually occurred hepatocellular necrosis. The vascular endothelial cells in the fibrous septa expressed factor VIII-related antigen, exhibited fenestration accompanied by basement membrane formation, and were surrounded by Ito cells. Most of the portal vein branches showed hypertrophic thickening of the smooth muscle layer, resulting in narrowing of the lumen. These vascular changes suggested that hemodynamic alterations of the intrahepatic circulation induced hepatocellular necrosis/apoptosis and played an important role in the pathogenesis of porcine serum-induced liver fibrosis in rats. — KEY WORDS: immunohistochemistry, liver fibrosis, porcine serum, ultrastructure.

MATERIALS AND METHODS

Animals: Fifty, 7-week-old male rats (Fischer 344/NSlc, Japan SLC Inc., Shizuoka), weighing approximately 150 g, were given an intraperitoneal injection of PS (JRH Biosciences, Lunexa, KS, U.S.A., Lot No. 4C2028) twice a week. The same lot of PS was used throughout the study. The rats were housed (two or three per cage) in polycarbonate cages and maintained under controlled conditions (temperature, 23 ± 2°C; humidity, 60 ± 5%). A commercial diet (CE-7, CLEA Japan Inc., Tokyo) and tap water were supplied ad libitum. The rats were euthanized under ether anesthesia by exsanguination via the abdominal aorta 7 days after the last injection for each treatment group. The spleen weight was measured to investigate the presence of portal hypertension and the degree of reaction against PS injection, and the mean values for control and treated groups were subjected to statistical analysis with Student’s t-test. Serum samples, obtained from rats at necropsy, were stored at −20°C until analyses for biochemistry and antibody titer against PS.

Experiment I: This experiment was designed to investigate time-related morphological changes of fibrosis. Rats were injected with a 0.5 ml of PS twice weekly for 3, 4, 5, 6 or 7 weeks. Control rats received 0.5 ml of physiological saline. Two treated rats and two control rats were euthanized at the time points mentioned above.

Experiment II: This experiment was designed to investigate the relationships among dose of PS, extent of fibrosis, and anti-PS antibody titer. Rats were injected with 0.5, 1.0 or 2.0 ml of PS twice weekly for 8 weeks. Five rats...
were used in each treated group. Five control rats were injected with 0.5 ml of physiological saline.

**Experiment III:** This experiment was designed to investigate the morphological characteristics of fully-developed hepatic fibrosis with complete septal formation. Five rats were injected with 1.0 ml of PS twice weekly for 16 weeks. Five control rats were injected with 1.0 ml of physiological saline.

**Enzyme-linked immunosorbent assay (ELISA):** Antibody titer against PS in serum from all rats in Experiments I, II and III was measured by ELISA. Microtiter plates (Corning Glass Works, New York, U.S.A.) were coated with PS diluted 1:400 in 0.06 M carbonate buffer (pH 9.6) and nonspecific sites of the plate were blocked with 1% bovine serum albumin (Sigma Chemical Co., St. Louis, MO, U.S.A.) in phosphate buffered saline containing Tween 20 (PBS-T) (pH 7.4) (Wako Pure Chemical Industries, Ltd., Osaka). Aliquots (50 µl) of test sera diluted duplycately in PBS-T were added to the wells and the plates were incubated for 2 hr at 37°C. The plates were washed five times with PBS-T to remove unbound antibodies. Aliquots (100 µl) of peroxidase-conjugated rabbit anti-rat immunoglobulins (DAKO A/S, Glostrup, Denmark) were added to each well and the plates were incubated for 2 hr at 37°C. After incubation, unbound antibodies were removed by washing with PBS-T. Bound antibodies were detected by adding the substrate, O-phenylene diamine (Sigma Chemical Co.) containing hydrogen peroxide. Light absorbance was measured at 492 nm using an ELISA reader (Seikagaku Kogyo Co., Inc., Tokyo). The anti-PS antibody titer of the treated groups was defined as the highest dilution of serum with an optical density two times higher than that of control rat serum.

**Biochemical analysis:** Activities of serum AST, ALT and ALP, concentrations of total protein, albumin and globulin, and the albumin/globulin ratio (A/G ratio) in sera obtained from all rats used in Experiments II and III were determined with an automated analyzer (Hitachi 736–10, Hitachi Co., Ltd.). Mean Values of these parameters were subjected to statistical analysis by Student’s t-test.

**Histopathology:** All lobes of the liver from each rat in Experiments I, II and III were fixed in 10% phosphate-buffered formalin, processed routinely, and embedded in paraffin. Histopathological examination except for comparing interlobar difference in extent of fibrosis was mainly performed on the left lateral lobe. Paraffin sections were cut and stained with hematoxylin and eosin (HE) and with special stains including Masson’s trichrome stain, periodic acid-Schiff (PAS) reaction with diastase digestion, Schmorl’s ferric-ferricyanide reduction stain, Perls’ Prussian blue stain, Orcein stain, and toluidine blue (pH 4.1) stain. To detect cytoplasmic lipids in Ito cells, formalin-fixed liver tissues were refixed in Luna’s fixative (50 ml of 2% osmium tetroxide, 50 ml of 5% potassium dichromate and 10 drops of glacial acetic acid) for 3 days at 4°C. In addition, the number of mitotic hepatocytes in the left lateral lobe tissue sections of control and treated rats from Experiments II and III was counted. In Experiment II, the extent of fibrosis in each lobe of the liver was classified in 4-grades (Grades 1: early stage; Grades 2 and 3: late stage; Grade 4: advanced stage) following to Fujiwara et al. [12] to facilitate interlobar comparison. To compare the extent of hepatic fibrosis in between individual rats, the left lateral lobe of each liver was investigated. Histological examination of the spleen was also performed to evaluate the degree of follicular hyperplasia.

**Immunohistochemistry:** Immunohistochemical examination of rat liver showing each stage of fibrosis was performed by the labeled streptavidin-biotin method using a Histofine kit (Nichirei Corp., Tokyo). Representative liver tissue from 2 rats in each stage was investigated. Primary antibodies used in the present study are shown in Table 1. The antibodies, except for vimentin, were applied to formalin-fixed, paraffin-embedded tissues. In the case of vimentin, methacarn (60% methanol, 30% chloroform, 10% glacial acetic acid) was used as fixative. After blocking endogenous peroxidase activity with 3% hydrogen peroxide in deparaffinized sections, normal rabbit or goat serum was applied to the sections to inhibit nonspecific reactions. The sections were treated with primary antibodies for 1 hr at 37°C, next with biotinylated rabbit anti-mouse IgG or goat anti-rabbit IgG for 10 min at room temperature, then with peroxidase-labeled streptavidin for 15 min at room temperature, and finally with 3, 3′-diaminobenzidine in 0.1 M Tris buffer (pH 7.6) containing hydrogen peroxide. The sections were washed with 0.1 M phosphate-buffered saline (PBS) (pH 7.4) after each step. Counterstaining was performed with Mayer’s hematoxylin stain. Immunostaining for proliferating cell nuclear antigen (PCNA) was performed.

on left lateral lobe of the liver from rats in Experiment III. Absolute counts of PCNA-immunoreactivity were made by assessing a minimum of 1,000 hepatocytes and were represented as a labelling index (LI).

Electron microscopy: Electron microscopical examination was performed on 2 livers from each group showing Grade 2 or 3 (Experiment II) and Grade 4 (Experiment III) fibrosis. Small blocks (1 mm^3) of liver were fixed in 2.5% glutaraldehyde/0.1 M phosphate buffer (pH 7.4) for 2 hr at 4°C, post-fixed in 1% osmium tetroxide/0.2 M phosphate buffer for 2 hr at 4°C, dehydrated in graded ethanol, and embedded in epoxy resin. Semi-thin sections were cut, stained with toluidine blue, and examined by light microscopy to find the target sites. Then, ultra-thin sections were cut, double-stained with uranyl acetate and lead citrate, and examined using an Hitachi H-300 transmission electron microscope at 75 kV.

RESULTS

Spleen weight: Spleen weight in the treated groups in all experiments showed a significant increase (p<0.01, data not shown), except for the rats treated with 0.5 ml of PS twice weekly for 8 weeks in Experiment II.

ELISA: Anti-PS antibody was detected in the serum samples obtained from all PS-treated rats in Experiments I, II and III. The anti-PS antibody titer had a tendency to increase in proportion to the duration of injection period (Table 2), however it did not correlate with the dose of PS, as shown in Table 3. The average antibody titer in 16-week-treated rats was one and a half times higher than that in 8-week-treated rats.

Biochemical analysis: As shown in Table 4, in PS-treated groups, no elevation of serum AST, ALT, or ALP activity was observed and the serum albumin concentration was within normal range. However, in PS-treated rats of experiments II and III, the total protein and globulin concentration was statistically higher and the A/G ratio was statistically lower than those of the control rats. In addition, the globulin concentration and A/G ratio varied in a dose-related manner.

Histopathology: In Experiment I, hepatic fibrosis first appeared at the 5th week post-initial injection (p.i.) of PS (Fig. 1). Most of the early fibrosis developed around central veins (CVs) near the hepatic capsule. Eosinophils occasionally infiltrated around CVs even at this early stage of fibrosis (5th week p.i.), but no mast cells were observed. Likewise, Schmorl reaction and Perl's Prussian blue stain revealed that lipofuscin- and hemosiderin-laden macrophages appeared frequently around CVs (Fig. 1) and in fibrous septa (FS) from the early (5th week p.i.) stage onwards.

Complete septal fibrosis was observed by the 7th week p.i., though the FS were still very delicate (Fig. 2). Cellular components around CVs and in the FS were spindle cells, mast cells, eosinophils, and macrophages. Luna's fixative-refixed, paraffin-embedded sections demonstrated the presence of a number of cells containing fat droplets in the FS. The walls of the portal vein branches were thickened due to hypertrophy of smooth muscle cells (SMCs), which resulted in narrowing of the lumens (Figs. 3a, b). This vascular change was observed concurrently with the occurrence of fibrosis (5th week p.i.). No remarkable changes were found in the control rat liver.

In Experiment II, there was no clear relationship between the extent of hepatic fibrosis and the dose of PS. The extent of fibrosis clearly varied among rats within each dose group (Table 3). Likewise, the number of mitotic hepatocytes did not correlate with the extent of fibrosis (data not shown). The lesions in the treated rat liver were

* Titer in each rat receiving 0.5 ml of PS. PS: Porcine serum.
The number of mast cells appeared to increase in proportion to the volume of collagen in the FS, but varied from area to area. Interlobar comparison showed that the extent of fibrosis in each rat tended to be strongest in the left lateral lobe and weakest in the right lateral lobe.

In Experiment III, the FS were wider and perivenular fibrosis was more evident than those of 8-week-treated rats at the same dose of PS in Experiment II. The degree of fibrosis was also more severe than that of the rats in Experiment II (Table 3). In Experiment III, the fibrosis occurred uniformly in all treated rats. In addition, hepatocellular changes such as necrosis/apoptosis (Fig. 4a), eosinophilic change (Fig. 4b) or fatty change (Fig. 4c), and proliferation of biliary ductules were frequently observed in the treated rats of Experiments III, but rarely observed in the treated rats in Experiment II. Areas of most advanced fibrosis (Grade 4, showing especially thick bands of collagen fibers) were abundant in elastic fibers varying in size (Fig. 5).

essentially identical to those observed in 7-week-treated rat liver from Experiment I. The number of mast cells appeared to increase in proportion to the volume of collagen in the FS, but varied from area to area. Interlobar comparison showed that the extent of fibrosis in each rat tended to be strongest in the left lateral lobe and weakest in the right lateral lobe.
No anisonucleosis, cellular atypia, or swelling of hepatocytes were observed in any group throughout all three experiments.

Mild follicular hyperplasia in the spleen was observed histologically in PS-treated rats of all experiments but there was no significant difference in degree of follicular hyperplasia among the treated groups.

**Immunohistochemistry:** Alpha-smooth muscle actin (α-SMA)-and desmin-positive cells appeared in the early FS (Fig. 6a). In late stage FS, almost all spindle cells showed triple positive reactions for α-SMA (Fig. 6b), desmin (Fig. 6c), and vimentin. Desmin immunoreactivity was higher in cells in and adjacent to the FS than in Ito cells within the hepatic lobules (Fig. 6c). However, α-SMA expression was limited to spindle cells around the CVs and in the FS and vascular SMCs. Vimentin expression was observed in all mesenchymal cells in the liver and proliferative biliary ductules. Most macrophages around the CVs and in the early and late stage FS showed positive reactions for both ED-1 (Fig. 6d) and ED-2. Vascular endothelial cells in the FS expressed factor VIII-related antigen (FVIII-RAg) (Fig. 6e), although sinusoidal endothelial cells (SECs) within the lobules were negative for this antigen. There was no significant difference in the number of PCNA-positive hepatocytes between control (LI: 0.68 ± 0.20%) and 16-week-treated (0.76 ± 0.15%) rat livers. Proliferative biliary ductules contained a high number of PCNA-positive cells. No PCNA-positive cells were observed in the FS.

**Electron microscopy:** Electron microscopic observation revealed that Ito cells (Fig. 7), fibroblasts, lymphocytes, plasma cells, lipofuscin- and/or hemosiderin-laden macrophages were present around the CVs and in the FS. Although only rarely observed, vascular endothelial cells in the FS had fenestrae accompanied by basement membranes, and were surrounded by Ito cells (Fig. 8). Occasionally, erythrocytes were observed in the Disse’s space (Fig. 9a) and in the cytoplasm of hepatocytes around CVs (Fig. 9b). These ultrastructural findings were detected in all livers showing Grades 2, 3 and 4 fibrosis but were most prevalent in Grade 4 fibrosis.

**DISCUSSION**

The pathogenesis of PS-induced rat liver fibrosis has yet to be clarified. There were no relationships among the dose of PS, the extent of fibrosis, and the anti-PS antibody titer in the present study. However, a correlation between the latter two factors has been described previously [27]. Biochemical analysis revealed increased serum globulin in treated rats in the present study, but the role of host immunoreaction against PS in the pathogenesis of this fibrosis model is still unclear. The class of immunoglobulins produced or the volume of immune complexes may have some relationship to this pathogenesis.

A number of macrophages with and without lipofuscin around CVs and in FS in the present study were considered to be Kupffer cells because of their immunoreactivity to both ED-1 and ED-2. The lipofuscin in these cells may be derived from phagocytosed hepatocytes with lipid peroxidation of the plasma membranes.

Ito cells of rats are desmin-positive [38]. In the present study, the immunoreactivity for anti-desmin antibody of Ito cells around CVs and in and adjacent to FS was more intense than that of Ito cells within the lobules, as previously
reported [7, 39]. Since Ito cells have shown an enhanced expression of desmin around damaged areas in the rat liver [25], presence of desmin-positive cells around CVs and in FS seen in the present study may represent a cellular reaction against hepatic injury in this model.

Septal fibroblasts in this model have been reported to be α-SMA-negative [8], but we detected α-SMA expression of the septal fibroblasts in the present study as seen in CCl₄-induced liver fibrosis [24, 30, 34]. However, no myofibroblast-like cells were observed in FS in the present study, just as none were observed in previous studies on PS-induced liver fibrosis in rats [1, 3, 7, 20, 31]. Ito cells in the areas of necrosis in human chronic active hepatitis have shown an increased intensity of immunostaining for α-SMA [11]. As in the case of desmin-expression, α-SMA-expression may also represent a reactive change in Ito cells in response to hepatocellular necrosis. Transformation of

rat Ito cells into myofibroblasts has been demonstrated in vitro [30, 37] and in vivo [34].

Hepatic fibrosis develops on account of incomplete hepatocellular regeneration following hepatocellular necrosis. Although the significance of hepatocellular necrosis in the liver fibrogenesis has been proposed by Popper [29], the PS-induced liver fibrosis model has been characterized by absence of an obvious hepatocellular necrosis [27]. In general, several findings such as presence of α-SMA-positive cells [11], desmin-positive cells [25], and macrophages [14, 16], and proliferation of elastic fibers [33] in the liver have been considered to be the results of hepatocellular necrosis. These findings were also observed in the present study, suggesting that hepatocellular necrosis/apoptosis developed in PS-treated rat liver and those changes were undetectable by light microscopy in the 8-week-treated rats because of a small number of injured cells and rapid phagocytosis by macrophages. Hepatocellular necrosis/apoptosis and degeneration were observed frequently in the 16-week-treated rat liver in the present study and these results may indicate an elevated frequency of hepatocellular injury.

It has been reported that hemosiderin-loaded macrophages appear around CVs at an early stage in CCl₄-induced rat liver fibrosis [30]. Ultrastructural study on dichloropropanol-induced acute hepatic necrosis revealed large gaps between SECs along with extravasation in conjunction with hepatocellular degeneration [13]. Hemosiderin in Kupffer cells in the present study may be derived from extravasated erythrocytes resulting from hepatocellular injury of endothelial damage inducing hyperpermeability.

Mast cell and eosinophil infiltration were frequently encountered around CVs and in FS in the present study. Mast cells are known to affect fibroblast activity [10]. A correlation may exist between collagen production and the accumulation of mast cells and eosinophils in PS-induced liver fibrosis in rats [31]. A single intraperitoneal injection of *Ascaris* cuticle induced eosinophilia, mast cell hyperplasia, and antibody production in rats [2]. Therefore, frequent infiltration of both types of cells in PS-induced liver fibrosis may indicate the occurrence of some kind of immunoreaction in the liver, but their significance is not known at present.

Presence of erythrocytes in the cytoplasm of hepatocytes and in the Disse’s space was occasionally demonstrated around CVs and adjacent to FS in the present study. Since hypoxia due to circulatory disturbance in the liver accelerates the pinocytotic activities of the hepatocytes [36], these findings may indicate the presence of hypoxic conditions in hepatocytes located between neighboring CVs in this model.

The endothelial cells expressing FVIII-RAg in FS may be SECs as suggested by ultrastructural findings in this study. Increased arterial blood supply in small hepatocellular carcinoma resulted in expression of FVIII-RAg in the SECs and sinusoidal capillarization [19]. FVIII-RAg expression in the SECs of FS in this model may indicate increased blood flow into the liver. These hemodynamic changes may develop as an adaptive phenomenon against altered intrahepatic circulation in this model.

Partial obstruction of the portal vein induced apoptosis of hepatocytes and resulted in atrophy of the left and median lobes and compensatory hypertrophy of the right and caudate lobes of the liver [17]. Interlobar differences in the extent of fibrosis were found in the present study. This concurrence in the distribution of lesions and the development of early FS from CVs near the hepatic capsule may suggest that fibrogenesis in this model followed the
vascular or hemodynamic changes in intrahepatic circulation.

In conclusion, hepatocellular necrosis/apoptosis develops in PS-treated liver fibrosis in rats, and may result from an adaptation to hemodynamic changes in the liver.

ACKNOWLEDGEMENTS. We thank Dr. Makoto Enomoto (Biosafety Research Center, Foods, Drugs, and Pesticides, Shizuoka, Japan) for reviewing this manuscript, and Dr. Jiro Sugimoto (Mitsubishi Chemical Corp., Yokohama Research Center, Yokohama, Japan) for biochemical analysis.
