(Received 7 November 1997/Accepted 14 July 1998)

ABSTRACT. The *Listeria monocytogenes*-carrying rates were 100% for listeriosis patients and 1.3% for healthy humans. The *L. monocytogenes* contamination rates for retail sliced beef (34.2%) and pork (36.4%) were significantly higher (p<0.05) than those for cattle (2.0%) and pigs (0.8%) and for cattle (4.9%) and swine (7.4%) carcasses. The percentages of serotypes 1/2a, 1/2b and 4b which are most dominant in human patients were high in isolates from fresh (90.0%) and processed (100%) fish and shellfish and imported natural cheese (96.7%). — key words: *Listeria monocytogenes*, meat, serotype

---

A number of cases of listeriosis caused by the intake of foods such as cheese, meat, ice cream and fish have been reported overseas since the beginning of 1980s [6, 8, 10] and *Listeria monocytogenes* serotypes 1/2a, 1/2b and 4b have been almost exclusively implicated in these incidents. Thus, listeriosis has been positioned as one of the important foodborne infections [14]. Although some 30 sporadic cases of listeriosis have been confirmed every year [3], their sources of infection are mostly unknown and such foodborne cases have not yet been reported in Japan. Therefore, it is necessary to investigate in detail the scope and degree of food contamination with *L. monocytogenes*. In this study, detection of *L. monocytogenes* was attempted on a large number of samples collected widely from humans including listeriosis patients, animals and foods in Japan and the isolates were serotyped on the basis of cellular and flagellar antigens.

For a period from 1988 through 1994, a total of 31,127 samples from listeriosis patients, healthy humans, animals, meat, fish and cheese were subjected to isolation of *Listeria monocytogenes*. As shown in Table 1, the *L. monocytogenes*-carrying rates were 100% for listeriosis patients and 1.3% for healthy humans. The *L. monocytogenes* contamination rates for retail sliced beef (34.2%) and pork (36.4%) were significantly higher (p<0.05) than those for cattle (2.0%) and pigs (0.8%) and for cattle (4.9%) and swine (7.4%) carcasses. The percentages of serotypes 1/2a, 1/2b and 4b which are most dominant in human patients were high in isolates from fresh (90.0%) and processed (100%) fish and shellfish and imported natural cheese (96.7%). — key words: *Listeria monocytogenes*, meat, serotype

---

A 1-g portion of stool and intestinal content samples was enriched in 9 ml UVM medium (Difco Laboratories, Detroit, Mich.) or EB medium (Difco). The swabs were each added to 9 ml of an enrichment medium. Samples of natural cheese (25 g) and meat and fresh and processed seabooods (10 g each) were each placed in a stomacher bag containing 225 ml or 90 ml of the enrichment medium, and homogenized for 1 min with a stomacher. The stomacher bags were incubated at 30°C for 48 hr. Two to three loopfuls of the cultured enrichment medium from the stomacher bags were streaked on a plate of Oxford agar medium (Oxoid, Unipath Ltd., Basingstoke, Hampshire, England) or PALCAM agar medium (Merck Co., Inc., Rahway, N.J.) supplemented with amphotericin B (Sigma Chemical Co., St. Louis, Mo.) at a concentration of 6 µg/ml to inhibit the growth of mycetes and the plates were incubated at 30°C for 48 hr. Slightly flat colonies with brownish color in the periphery, which is characteristic of *Listeria*, were subcultured on Tryptose Agar medium (Difco). The colonies developed on Tryptose Agar medium were observed under a low power microscope with obliquely reflected light and blue greenish colonies were selected [12]. Identification was carried out by Gram staining, catalase and VP tests, observation of umbrella-like growth and motility in semiliquid Brain Heart Infusion Agar medium (Difco), utilization of rhamnose, xylose and mannitol, β-hemolysis on 5% sheep blood Tryptic Soy Agar medium (Difco) and the CAMP test [12] with *Staphylococcus aureus* JTE 88–221 and *Rhodococcus equi* JTE 89–387.

The factor sera were prepared by hyperimmunizing rabbits (Japan Laboratory Animals, Inc., Tokyo) with each of 12 reference strains, *Listeria monocytogenes* JTE 88–178 to JTE 88–180 and JTE 88–188 to JTE 88–191, by the method of Seeliger and Höhne [11]: 11 kinds of somatic (O) antigen factor sera and four kinds of flagellum (H) antigen factor sera were obtained. Serotyping was conducted by O and H agglutination reactions on microplates [1]. Description of the serotypes of the isolates was followed after Seeliger and Höhne [11].

As shown in Table 1, the *L. monocytogenes*-carrying rates...
were 100% and 1.3% for listeriosis patients and stool specimens of healthy humans, respectively. In animals examined, the rates were 0.9, 2.0 and 0.8% for dogs, cattle and pigs, respectively. Rats showed a relatively high rate being 6.5%. In foods, the contamination rates were 3.0, 7.4 and 3.0% for cattle and swine carcasses and sliced horse meat, respectively, and 2.6% for cheese and 1.3 and 5.3% for fresh and processed fish and shellfish, respectively. Sliced beef, pork and chicken showed considerably high rates of 34.2, 36.4 and 37.5%, respectively.

A total of 1,195 isolates were classified into 15 serotypes and four serotypes 1/2a, 1/2b, 1/2c and 4b were most prevalent accounting for 95.1% of the total isolates. Isolates from listeriosis patients were classified exclusively into three serotypes 1/2a, 1/2b and 4b. The isolates from stool specimens of healthy humans, cheese, fish and shellfish were almost exclusively identified as one of the three serotypes and those from animals and raw meats were mostly identified into the four prevalent serotypes. The serotypes other than the four prevalent ones were 1, 3b, 3c, 4a, 4ab, 4b(x), 4c, 4d, 4e, 4g and 4. Meat and fish were contaminated with \textit{L. monocytogenes} three serotypes 1/2a, 1/2b and 4b with the progress of their processing steps.

In this study, a large number of samples collected widely from various sources in Japan were investigated for \textit{L. monocytogenes}. Processed raw meat, fish and shellfish samples were included in this study to examine for the influence of processing on the contamination with \textit{L. monocytogenes}. The \textit{L. monocytogenes} contamination rates of the stool specimens of healthy humans, intestinal contents of animals, livestock foodstuffs and seafoods were essentially similar to those reported in other countries [7].

The primary source of \textit{L. monocytogenes} contamination of carcasses is assumed to be the contents of the large intestine of slaughtered animals [13]. In this study, although it is not proper to compare the \textit{L. monocytogenes} contamination rates of carcasses (surface swabs) and feces and retail sliced meat (in grams), as their sampling methods were different from each other, the contamination rates of the retail sliced beef (34.2%) and pork (36.4%) were significantly higher (p<0.05) than those of the cattle (4.9%) and swine (7.4%) carcasses and of the intestinal contents of cattle (2.0%) and pigs (0.8%). Similarly, the percentage of each of the three serotypes 1/2a, 1/2b and 4b, which are main causal serotypes of listeriosis, was higher (p<0.05) in isolates from sliced beef than in those from intestinal contents of cattle and cattle and swine carcasses. In pig intestinal isolates, the percentages of the three serotypes were considerably high; however, the rates were lowered in isolates from swine carcasses to the level similar to those in isolates from cattle carcasses and then became high in sliced pork isolates to the level similar to those in sliced beef isolates. These results indicate that raw meat is contaminated with \textit{L. monocytogenes} three serotypes 1/2a, 1/2b and 4b with the progress of processing steps and that, like the poultry-processing environment concerning \textit{L. monocytogenes} contamination [5], slaughterhouses and meat processing environments are more important as a source of
**L. monocytogenes** contamination of the meat than intestinal contents of slaughtered animals.

Caution is needed in handling retail meat products as they can be a potent source of contamination leading to listeriosis. However, retail raw meat products are less likely to be the direct source of infection so long as their handling and method of cooking are adequate and since meat products are usually ingested after cooking and the bacterial content per gram is often less than \(10^2\) [4, 9].

**L. monocytogenes** contamination rate of retail sliced horse meat was extremely low as compared with the corresponding retail sliced beef, pork or chicken. This may suggest that much attention is being paid to the processing of horse meat to avoid bacterial contamination because it is often eaten raw as a delicacy in Japan.

The **L. monocytogenes**-carrying rate (6.5%) in rats was higher (p<0.05) than those of dogs (0.9%), cattle (2.0%) or pigs (0.8%). Furthermore, the percentage (61.5%) of the three serotypes 1/2a, 1/2b and 4b, which often most cause human disease, in rat isolates was the highest among the animals examined other than healthy humans and the carrier rate (4.0%) of the three serotypes in rats was also higher (p<0.05) than those in such other animals examined as dogs (0.4%), cattle (0.3%) and pigs (0.5%). Although approximately one thirds of human listeriosis cases in foreign countries are known to be foodborne, the remaining major cases are still unknown of the source of infection [9]. It might be possible to consider that rats play a role as a contaminator in the environment such as restaurants in the buildings in cities.

The **L. monocytogenes** contamination rate (1.3%) of fresh fish and shellfish was rather low in comparison with that (about 36%) for the retail sliced meat. The bacterial count per gram of fresh fish and shellfish has been reported to be as low as less than \(10^2\) [9], in contrast to \(10^3\) to \(10^7\) in cheese [9] which has often been regarded to be closely associated with the incidence of listeriosis. Moreover, fresh seafoods eaten without cooking is rarely stored for an extended period of time and the bacterial content in such seafoods at the time of ingestion could seldom be high even if **L. monocytogenes** is capable of proliferation at low temperatures. Therefore, fresh seafoods will seldom be the source of infection with **L. monocytogenes**.

As for processed seafoods that are ready-to-serve without cooking such as smoked or flaked salmon, boiled shellfish and so forth, the **L. monocytogenes** contamination rate (5.3%) was low as compared with those of retail sliced meat. However, the isolates from processed seafoods all belonged to serotypes 1/2a, 1/2b or 4b. Furthermore, processed seafoods are kept refrigerated for a relatively long period of time like natural cheese and **L. monocytogenes** may grow during the storage. Therefore, the processed seafoods may be a possible source of **L. monocytogenes** infection. This has already been pointed out also by Jemmi [2].

The three serotypes of **L. monocytogenes** 1/2a, 1/2b and 4b are considered to be of particular importance as causal serotypes of listeriosis since their percentages are overwhelmingly high in the isolates clinically collected from diseased animals and human patients [8]. In this study, Japanese isolates derived from patients were also all classified into any one of these serotypes. Although the **L. monocytogenes**-carring rates of stool specimens of healthy humans was similar to those of other animals examined, such a high rate as 94.7% of healthy human isolates were classified into the three serotypes, suggesting that if the high risk groups such as infants, aged people and those with immunodeficiency become carriers of **L. monocytogenes**, chances are that they are likely to develop listeriosis.
